Temperature fell from 103°F. to normal in twenty-four hours, and remained normal until the fifth day when it rose to 102°F. He was found to have painful swelling of the left knee from which a purulent fluid was aspirated. On the following day the left elbow was swollen, and the day after, the right knee and elbow. On no occasion could any organism be cultured from the joints. The L. knee and L. elbow subsided after single aspiration and penicillin replacement; the right elbow recovered spontaneously; the right knee required aspiration every few days for two weeks. Besides local penicillin he has had 5,000 units intramuscularly four-hourly for eighteen days.

He now has full movement in all joints, and a little fluid still in the right knee.

Stereoscopic skull X-rays reveal thickening of the greater wing of the sphenoid with erosion of the anterior clinoid processes, and gross widening of both optic foramina to about three times normal size for age.

Cerebrospinal fluid examination gave a pressure of 95 mm., a protein content of 90 mg.%, cells absent, sugar 65 mg.% and chlorides 740 mg.%. Wassermann reaction of the blood and C.S.F. was negative. Mantoux: 1:1000 negative.

Biopsy of lump in subcutaneous tissues of scalp was reported as having the histological appearance of a soft fibroid undergoing mucoid degeneration (Dr. Martin Bodian).

Discussion.—The case resembles those described by Cushing (1923), and Wyllie (1924) of glioma of the optic chiasm invading the nerve sheaths; of the former's 18 cases, 6 showed evidence of generalized neurofibromatosis, while Davies (1940) has found in the literature since 1870, 38 cases of glioma of the optic chiasm in association with neurofibromatosis, in 12 of which there was an hereditary element.

Familial Hæmolytic Anæmia.—CHARLES PINCKNEY, F.R.C.P.

D. R., male, aged 6 months. Sent to hospital with history of bronchitis and pallor since birth, which has increased recently. A first baby, birth-weight 7 lb. 10 oz., normal labour, not breast-fed. Taking well till previous week when developed bronchitis.

Father had splenectomy; report on grandfather as having had splenectomy.

On examination.—Marked pallor, signs of generalized bronchitis, spleen enlarged and firm, half-way to umbilicus.

12.3.46: Admitted to hospital. Investigations: Hb. 35%, reticulocytes 30%. Fragility test—commencing hæmolysis in 0.72% saline. Blood transfusion given: Hb. raised to 100%.

Discharged well but spleen still enlarged.

Seen again in Out-patients, 23.4.46; weight gain satisfactory, but increase of anæmia present. Investigation showed R.B.C.' 2,350,000; Hb. 40%; reticulocytes 1%. Admitted for further transfusion and splenectomy.

POSTSCRIPT.—Child has been seen in Out-patients department since. He appears to be perfectly normal with Hb. 80% and fragility test is now normal.—C. P.

Pneumococcal Empyema—Treated with Penicillin.—M. E. HUGHES, M.B., B.S. (for H. M. M. MACKAY, F.R.C.P.).

B. D., male child aged 8 months. Admitted 22.3.46 with a history of a febrile illness and cough seven weeks previously, a recurrence of symptoms and "heavy" breathing two weeks before admission.

On admission T. 99.4°F.; P. 144; R. 46. Child was very ill and pale with signs of a large effusion in the left side of his chest with displacement of the heart to the right. Radiography confirmed the presence of a large effusion on the left side and the heart was displaced completely across the mid-line into the right side of the chest. Aspiration produced 80 c.c. of thick green pus which on culture grew a penicillin-sensitive pneumococcus.

The child was treated with daily aspirations and intrapleural penicillin, using 40,000 units in a volume of saline equal to half the volume of pus aspirated on each occasion. The volume of pus decreased daily and on the fifth day no pus was obtained, and on two subsequent occasions no pus was obtained.

Radiologically the left side of the chest cleared steadily. Convalescence was interrupted by the development of a pneumonic consolidation at the right base which was treated with systemic penicillin and cleared rapidly. The anæmia failed to respond to iron therapy and a transfusion of 250 c.c. of blood was given.

The child's condition improved rapidly and he gained in weight. On discharge there were no abnormal physical signs in his chest and X-ray showed only very slight loss of translucency at the left base.

Arachnodactyly with Amyoplasia Congenita.—E. M. KINGSLEY-PILLERS, M.B., B.Chir. (for H. M. M. MACKAY, F.R.C.P.).

David L., born 27.2.46. The baby was first seen at 10 days old and had not seemed normal since birth. The arms were flexed at the elbow-joints and could not be extended beyond 90 degrees. The knees were flexed with marked limitation of extension. The hands were large with long spidery fingers and the feet were long and thin. The foot

changes demonstrate that prenatal and neonatal glycogen metabolism differs from that occurring later. He considers that increased insulin sensitivity and probably faulty glycogenolysis to be operative, and not absolute hyperinsulinism.

In the newborn of the diabetic mother, hypoglycæmia may be responsible for severe reactions, convulsions, and collapse, but this is generally remedied by glucose feeds. Neonatal hypoglycæmia may be intensified in its effects by intracranial injury or adrenal hæmorrhage.

Rector and Jennings observed the occurrence of hypoglycæmia with convulsive effects in children, aged 1 to 3 years (11 cases). They suggest it is due to intermittent functional hepatic disorder with temporary depletion of glycogen reserve and that most cases are amenable to conservative management, especially a diet high in carbohydrate and that the prognosis is infinitely better than it is for older patients with hypoglycæmia of organic origin. Whilst recognizing that hypoglycæmia is not a frequent cause of convulsions in childhood they suggest that blood sugar studies should be made in cases of obscure convulsion disorder in childhood.

Graham and Hartmann report a case of a girl aged 1 year, with blood sugar 18 mg.%, who was benefited by partial pancreatectomy.

In hypoglycæmia the symptoms and signs may be considered as an ordered depression of the cerebral levels from the higher to the lower, and the clinical effects would seem to bear a relationship to a rate of fall as well as a degree of fall in the blood sugar. The symptoms may vary in the same patient under the same degree of hypoglycæmia. There is considerable variation in individual sensitivity to insulin. Sometimes even though the blood sugar may decline to 30 mg.% reaction may be delayed up to thirty to sixty minutes and in fact may synchronize with a reactionary rising level of blood sugar. Notably also, flushing and sweating varies considerably in the patients. There is no doubt that there is a personal cerebral sensitivity in the hypoglycæmia state, and this may be compared with alcohol intoxication and the behaviour patterns may be considered in relation to hypothalamic responses.

CASE I.—M. T. Spontaneous hypoglycæmia. First baby, 40 weeks' pregnancy, birth-weight 7 lb., normal delivery. Eight hours' labour. Admitted on 30.1.46, aged 4 weeks, with a history of being quite well until two days previously when he had gone off his feeds and become constipated. He had had several small convulsions on the day of admission. He was found to have some umbilical sepsis with a palpable liver and inflammation of the throat and ears. A tentative diagnosis of neonatal infection was made and treated with sulphonamide and penicillin. Intravenous infusions of 5% dextrose were given from 30.1.46 to 1.2.46. Frequent convulsions occurred between 3 to 6.2.46, during which the calorific value of his feeds was increased although the sugar remained at the same level (50 grammes per day). Infantile tetany was suspected, but the blood calcium was normal (10.7 mg.). On discharge on 12.2.46 he had gained weight from 6 lb. 5 oz. to 6 lb. 12 oz. and was chiefly breast-fed with a complementary feed containing 7% carbohydrate. In hospital he was fed at three-hourly intervals with the 3 a.m. feed omitted, but on his return home the 12 midnight feed was also omitted.

Readmitted on 15.2.46 with a history of having had several convulsions per day since discharge three days previously, although he had been taking his feeds well. On examination he was apparently unconscious with twitching of his limbs and face. Respiration was very irregular and shallow. No signs of infection were found. As he was not taking by mouth, intravenous infusions of 5% dextrose were given on February 15 and 16, 1946. The epileptiform state ceased during the night of the 15th-16th. Lumbar puncture on the 16th and 21st did not show any diagnostic signs of meningitis or of cerebral hæmorrhage; the protein was 30 mg. per 100 ml. and the sugar was absent.

The convulsions continued, about 6 to 7 being observed per day. He was noticed to sweat profusely during these attacks of twitching and this together with the low C.S.F. sugar suggested a diagnosis of hypoglycæmia. Blood sugar on 1.3.46 was 23 mg.%, the specimen being taken three hours after a feed. The feeds were increased from 42 grammes sugar daily to 70 grammes including a feed at 12 midnight; the convulsions were controlled. On 5th the response to an injection of adrenalin, 2 ml. of 1/1,000 solution was found from blood-sugar readings to be normal. The convulsions persisted in spite of increasing the feed on 13th to 50 grammes sugar daily. On 19th a diurnal glucose curve gave low readings falling to 20 mg.% at midnight, so the feeds were increased to 68 grammes sugar daily with a feed at midnight. As he had no fits for a month he was allowed home. Just before discharge the interval between feeds was increased to four hours and the midnight feed omitted. He returned to the Out-Patient Department a week later having had further convulsions. The sugar content of the feeds was increased to 87 grammes per day; three-hourly, with a feed at midnight. While in hospital he never showed any intolerance to the high percentage of sugar in the feeds, and on this high carbohydrate appeared to be generally better, but diurnal blood-sugar readings showed moderate low level and undoubtedly hypoglycæmia was intermittently present.

The clinical progress has been poor despite high carbohydrate intake. The baby now shows evidence of cerebral damage and a condition of decorticate rigidity has appeared. Insulin depression curve on 68 grammes carbohydrate diet showed a minimum reading of 44 mg. The lowest blood-sugar diurnal variation—25 mg. Liver, viscera, n.d.

His mother's blood-sugar and glucose tolerance curves were found to be normal.

CASE II.—J. P. Spontaneous hypoglycæmia. Birth-weight 8 lb., forty-eight hours' labour. Possibly some cerebral damage at birth. Forceps delivery. At 2 days old, went limp, did

Suppurative Arthritis following Bronchopneumonia.—(Under W. G. WYLLIE, F.R.C.P.)

T. G., male, aged 4½ years. History of bronchopneumonia in March 1946 followed fourteen days later (27.3.46) by pain, stiffness and swelling in the left knee.

Admitted to hospital 1.4.46. On examination the chest was clear. The left knee contained fluid. Temperature 100°F.

Purulent fluid was aspirated from his knee, from which a hæmolytic streptococcus was grown. 10,000 units of penicillin were injected into his knee-joint, and he was given 10,000 units four-hourly intramuscularly for ten days.

After three days there was considerable improvement, and in eight days he was symptomless.

Suppurative Arthritis of Right Elbow following Mastoiditis.—(Under B. SCHLESINGER, F.R.C.P.)

J. D., female, aged 9 years.

Left mastoid operation two years ago.

27.2.46: Admitted to hospital with pain and purulent discharge from left ear, and swelling behind the ear.

Mastoid reopened and necrotic remains of mastoid air cells removed. Penicillin applied locally, 3,000 units four-hourly for five days. Wound healed satisfactorily. Discharged from hospital 20.3.46.

25.3.46: Right otitis media, which cleared in a few days on sulphonamide treatment.

On 2.4.46 she began to complain of pain in her right arm, and was readmitted to hospital on 7.4.46 with a temperature of 101°F. and signs of fluid in her right elbow. Aspirated fluid was purulent and grew a hæmolytic streptococcus. On the two days following admission penicillin (10,000 units) was injected into the joint, and she was also given 10,000 units four-hourly intramuscularly for ten days.

She became afebrile in four days, there was no further accumulation of fluid in her elbow, and she was discharged fit after seventeen days.

[May 25, 1946]

Spontaneous Hypoglycæmia in Infancy and Childhood

By A. V. NEALE, M.D.

IN the normal regulation of the blood sugar several factors are physiologically integrated, including hormones of the anterior pituitary gland, islets of Langerhans, adrenal cortex and medulla, glycogen-glucose interchange, tissue metabolism, renal threshold, diet, and possibly nervous mechanisms particularly in the hypothalamus.

The hormones of the anterior pituitary favour gluco-neogenesis, in opposition to insulin, and counteract the peripheral action of insulin in the tissues. In hypophysectomy there is a hypersensitivity to insulin with possibly hypoglycæmia.

The brain of the fœtus and of the newborn is probably less susceptible to permanent damage by anoxia. It is suggested that the tolerance of young dogs to anoxia and hypoglycæmia is related to relatively low cerebral metabolic rate, and an anaerobic source of energy. In the adult the reverse is the case, and is related to the greater susceptibility of the higher centres, and cerebral tissue to anoxia and hypoglycæmia. In fatal hypoglycæmia there is widespread degeneration and necrosis of nerve cells in the cerebral cortex, and basal ganglia, this being probably due to failure of vital oxidative processes from lack of substrate glucose and worsened by subsequent vasomotor disturbance.

Hypoglycæmia may occur in numerous clinical conditions including adrenal insufficiency; pituitary insufficiency, e.g. tumour, cyst, or atrophy; Von Gierke's hepatomegalia glycogenica; hypothyroidism; renal glycosuria and low carbohydrate diet; prematurity; and possibly in hypothalamic lesions. Parris and Ingram observed the occurrence of hypoglycæmia in animals with experimental lesions in the anterior hypothalamus, particularly in the neighbourhood of the paraventricular nucleus. There are cases of spontaneous hypoglycæmia in which the cause is not definite. True hyperinsulinism, e.g. islet tumour, is extremely rare in childhood.

Hypoglycæmia may occur in the newborn, during the first several days of life. This is probably due to imperfect endocrine regulation, with relative hyperinsulinism or defective glycogenolysis. Hartmann and Jandon state that hypoglycæmia during the first four or five days of life occurs quite frequently in normal newborn infants, and seems to be due to an imperfectly developed regulatory mechanism which creates a state of functional hyperinsulinism.

Van Creveld observes that the glycogen of the newborn shows the interesting difference that relatively large amounts of adrenalin are required for its mobilization and various

changes demonstrate that prenatal and neonatal glycogen metabolism differs from that occurring later. He considers that increased insulin sensitivity and probably faulty glycogenolysis to be operative, and not absolute hyperinsulinism.

In the newborn of the diabetic mother, hypoglycaemia may be responsible for severe reactions, convulsions, and collapse, but this is generally remedied by glucose feeds. Neonatal hypoglycaemia may be intensified in its effects by intracranial injury or adrenal haemorrhage.

Rector and Jennings observed the occurrence of hypoglycaemia with convulsive effects in children, aged 1 to 3 years (11 cases). They suggest it is due to intermittent functional hepatic disorder with temporary depletion of glycogen reserve and that most cases are amenable to conservative management, especially a diet high in carbohydrate and that the prognosis is infinitely better than it is for older patients with hypoglycaemia of organic origin. Whilst recognizing that hypoglycaemia is not a frequent cause of convulsions in childhood they suggest that blood sugar studies should be made in cases of obscure convulsion disorder in childhood.

Graham and Hartmann report a case of a girl aged 1 year, with blood sugar 18 mg.%, who was benefited by partial pancreatectomy.

In hypoglycaemia the symptoms and signs may be considered as an ordered depression of the cerebral levels from the higher to the lower, and the clinical effects would seem to bear a relationship to a rate of fall as well as a degree of fall in the blood sugar. The symptoms may vary in the same patient under the same degree of hypoglycaemia. There is considerable variation in individual sensitivity to insulin. Sometimes even though the blood sugar may decline to 30 mg.%, reaction may be delayed up to thirty to sixty minutes and in fact may synchronize with a reactionary rising level of blood sugar. Notably also, flushing and sweating varies considerably in the patients. There is no doubt that there is a personal cerebral sensitivity in the hypoglycaemia state, and this may be compared with alcohol intoxication and the behaviour patterns may be considered in relation to hypothalamic responses.

CASE I.—M. T. Spontaneous hypoglycaemia. First baby, 40 weeks' pregnancy, birth-weight 7 lb., normal delivery. Eight hours' labour. Admitted on 30.1.46, aged 4 weeks, with a history of being quite well until two days previously when he had gone off his feeds and become constipated. He had had several small convulsions on the day of admission. He was found to have some umbilical sepsis with a palpable liver and inflammation of the throat and ears. A tentative diagnosis of neonatal infection was made and treated with sulphonamide and penicillin. Intravenous infusions of 5% dextrose were given from 30.1.46 to 12.46. Frequent convulsions occurred between 3 to 6.2.46, during which the caloric value of his feeds was increased although the sugar remained at the same level (50 grammes per day). Infantile tetany was suspected, but the blood calcium was normal (10.7 mg.). On discharge on 12.2.46 he had gained weight from 6 lb. 5 oz. to 6 lb. 12 oz. and was chiefly breast-fed with a complementary feed containing 7% carbohydrate. In hospital he was fed at three-hourly intervals with the 3 a.m. feed omitted, but on his return home the 12 midnight feed was also omitted.

Readmitted on 15.2.46 with a history of having had several convulsions per day since discharge three days previously, although he had been taking his feeds well. On examination he was apparently unconscious with twitching of his limbs and face. Respiration was very irregular and shallow. No signs of infection were found. As he was not taking by mouth, intravenous infusions of 5% dextrose were given on February 15 and 16, 1946. The epileptiform state ceased during the night of the 15th-16th. Lumbar puncture on the 16th and 21st did not show any diagnostic signs of meningitis or of cerebral haemorrhage; the protein was 30 mg. per 100 ml. and the sugar was absent.

The convulsions continued, about 6 to 7 being observed per day. He was noticed to sweat profusely during these attacks of twitching and this together with the low C.S.F. sugar suggested a diagnosis of hypoglycaemia. Blood sugar on 1.3.46 was 23 mg.%, the specimen being taken three hours after a feed. The feeds were increased from 42 grammes sugar daily to 70 grammes including a feed at 12 midnight; the convulsions were controlled. On 5th the response to an injection of adrenalin, 2 ml. of 1/1,000 solution was found from blood-sugar readings to be normal. The convulsions persisted in spite of increasing the feed on 13th to 50 grammes sugar daily. On 19th a diurnal glucose curve gave low readings falling to 20 mg.% at midnight, so the feeds were increased to 68 grammes sugar daily with a feed at midnight. As he had no fits for a month he was allowed home. Just before discharge the interval between feeds was increased to four hours and the midnight feed omitted. He returned to the Out-Patient Department a week later having had further convulsions. The sugar content of the feeds was increased to 87 grammes per day; three-hourly, with a feed at midnight. While in hospital he never showed any intolerance to the high percentage of sugar in the feeds, and on this high carbohydrate appeared to be generally better, but diurnal blood-sugar readings showed moderate low level and undoubtedly hypoglycaemia was intermittently present.

The clinical progress has been poor despite high carbohydrate intake. The baby now shows evidence of cerebral damage and a condition of decorticate rigidity has appeared. Insulin depression curve on 68 grammes carbohydrate diet showed a minimum reading of 44 mg. The lowest blood-sugar diurnal variation—25 mg. Liver, viscera, n.a.d.

His mother's blood-sugar and glucose tolerance curves were found to be normal.

CASE II.—J. P. Spontaneous hypoglycaemia. Birth-weight 8 lb., forty-eight hours' labour. Possibly some cerebral damage at birth. Forceps delivery. At 2 days old, went limp, did

not feed until 8 days old, sucked well at 14 days, progress thereafter good. At 8 months suddenly went limp. Remained so for three days. Recovered after further five days. At 1 year 3 months, sudden collapse. Remained limp for some days and improved on glucose. Several short attacks of this kind. A week or so later—vomiting, and screamed for two hours, and was noticed to be staggering about. Became very limp and then became deeply unconscious. Admitted to hospital in a stuporous state. Limbs flaccid, plantar reflexes extensor. C.S.F.—absence of sugar. Blood sugar 38 mg.%. Intravenous glucose given. Some minutes after glucose child became more awake, colour improved, movements more purposive. Child smiled, rubbed her nose, but did not speak.

Child feeds satisfactorily, and progressed well until a month later when hypoglycaemic attack occurred without convulsions. Thought to be asleep but could not be roused. Blood sugar 35 mg.%. Adrenalin 5 ml. of 1/1,000 sol. revived patient within ten minutes. This child has periodic spontaneous hypoglycaemic reactions often associated with vomiting, but no definite convulsions. Present condition satisfactory. Attacks only occasional. Diurnal variation showed minimal readings of 45 mg.%. Attacks very much less frequent. No clinical evidence of any visceral abnormality. Parents healthy. Other children in family healthy.

CASE III.—R. H. Spontaneous hypoglycaemia. Nutritional history normal. At the age of 3 years found in coma one morning. Clinical examination negative apart from toneless muscles, rapid feeble pulse. Became rapidly worse and appeared to be on the verge of death with breathing feeble and shallow. Blood sugar 26 mg.%. C.S.F. sugar 12 mg.%. Intravenous glucose given and 5 ml. of adrenalin which caused rapid improvement. Intravenous discontinued and child took food well for a time, and then refused entirely; blood sugar fluctuated at low levels. Insulin depression curve showed minimal reading of 47 mg. Was put on full diet and discharged home as satisfactory. Nine months later the boy was brought, in coma, to the Casualty Department. Two and a half ounces of glucose in water were passed into the stomach and in ten minutes consciousness was regained. No further attacks have occurred and the boy seems to have maintained improvement on a diet rich in fat and poor in carbohydrate. Present diurnal blood-sugar readings normal.

CASE IV.—P. M. I. Epilepsy with associated hypoglycaemia. Well until aged 10 years when menstruation commenced and slight convulsions synchronously. Occasional but definite epileptiform attacks occurred just before a meal and all occurred a few days after the end of a menstrual period. General physique and mental level good. Minimal blood sugar and diurnal variation 50 grammes %. E.E.G. showed definitely abnormal reading which is referred to as being of diffuse type rather than local, and therefore is in accordance with diagnosis of idiopathic epilepsy aggravated by hypoglycaemia phases.

CASE V.—J. M. Pituitary cachexia, with increased insulin sensitivity. No hypoglycaemia symptoms. At the age of 8 appeared in a grossly emaciated condition with weakness and all the signs of pituitary insufficiency. Pathologist's examination showed a cyst of the pituitary gland. Diurnal variation of the blood sugar showed minimal reading of 45 mg.

CASE VI.—M. B. Anorexia nervosa. No hypoglycaemia. In contrast with the case of J. M., in this patient—although similarly and grossly wasted—diurnal variation showed normal readings, and at no time any hypoglycaemia.

The Treatment of Coeliac Disease with Vitamin B Complex and Liver Extract

By ERIC C. ALLIBONE, M.D.

ROSS (1936) showed that the administration of liver extracts improved the glucose tolerance in coeliac disease. Anderson (1945) had noticed that giving a mixture of five of the vitamin B fractions improved the appetite in this condition. May, McCreary and Blackfan (1942) using both parenteral liver and vitamin B complex obtained rapid clinical improvement with a rise in the vitamin A absorption tests, the patients being kept on a normal diet. Paterson, Pierce and Peck (1944) using the same method as May *et al.* confirmed the clinical improvement in coeliac disease but did not obtain such good results in the vitamin A and oral glucose tolerance tests.

This paper records the results of the cases of coeliac disease treated in this hospital on the above lines. Thanks to the kindness of Professor Struthers of Montreal and Messrs. John Wyeth and Brothers Ltd., London, it was possible to get the same preparations as were used in America by May and his co-workers.

Method.—After the initial investigations, daily intramuscular injections of vitamin B (4 c.c.) alternating with liver extract (2 c.c.) were given. The duration of the course

was three weeks in the first 15 cases and was then raised to six weeks in a further 8 cases. After reassessment the patients were put on oral treatment consisting of proteolized liver, vitamin B complex, vitamins A, D, and C, and iron. Whenever feasible an ordinary ward diet was given. The duration of the oral therapy varied between six months and a year.

The diagnosis was made on the history, physical signs and stool analysis. The duodenal enzymes were not estimated as a routine. In no case, except one which proved fatal, were respiratory symptoms prominent or persistent, though 11 cases had signs on admission of a recent upper respiratory infection.

FIG. 1.—Composite intravenous glucose tolerance curves in coeliac disease.

FIG. 2.—Composite oral glucose tolerance curves in coeliac disease.

The age of onset of symptoms varied from birth to 33 months with an average of 14 months. The average age at commencement of treatment was 3 years 5 months though, if 4 mild cases in older children were to be excluded, this figure was reduced to 2 years 2 months.

RESULTS

Twenty-three cases were investigated. Of these two died. One had recurrent attacks of bronchitis and contracted a fatal pneumonia while in another hospital. An autopsy was refused. It is possible that this case may have had a pancreatic fibrosis. The other, while on oral therapy, relapsed with diarrhoea followed by generalized weakness. A fortnight after the onset of the recrudescence he was admitted to hospital and died five days later. The post-mortem examination showed an enteritis, otitis media with a terminal bronchopneumonia. Histologically there was atrophy of the secretory tissue of the pancreas with increase of the connective tissue. There was no evidence of chronic bronchial suppuration. Tiny patches of demyelination of the posterior columns of the spinal cord with hydropic degeneration of the heart muscle suggested a diagnosis of beriberi. Dr. H. S. Baar, who performed the autopsy, was unable to say whether the pancreatic changes were primary or secondary.

Three cases defaulted after going home on oral therapy. Of the remaining 18 cases, 6 had to be put on a fat-free diet at the end of the course of parenteral treatment because their clinical condition was deteriorating. A further 4 were changed to a low fat diet as a result of the final assessment after six to twelve months' oral treatment, leaving 8 patients well enough to remain on an ordinary diet.

Although initially under height, growth occurred at the normal rate during treatment. A deficiency in weight was decreased. The figures for weight cannot be considered to be a reliable index of progress, owing to fluctuations in the bulk of the intestinal contents (Table I).

TABLE I.—AVERAGE HEIGHT AND WEIGHT IN COELIAC DISEASE.

	Before treatment	After treatment
Height, expressed as a percentage of the expected height for the age (12 cases) ...	85	90
Weight, expressed as a percentage of the expected weight for the age ...	71	76
Weight, expressed as a percentage of the expected weight for the height ...	91	96

not feed until 8 days old, sucked well at 14 days, progress thereafter good. At 8 months suddenly went limp. Remained so for three days. Recovered after further five days. At 1 year 3 months, sudden collapse. Remained limp for some days and improved on glucose. Several short attacks of this kind. A week or so later—vomiting, and screamed for two hours, and was noticed to be staggering about. Became very limp and then became deeply unconscious. Admitted to hospital in a stuporous state. Limbs flaccid, plantar reflexes extensor. C.S.F.—absence of sugar. Blood sugar 38 mg.%. Intravenous glucose given. Some minutes after glucose child became more awake, colour improved, movements more purposive. Child smiled, rubbed her nose, but did not speak.

Child feeds satisfactorily, and progressed well until a month later when hypoglycaemic attack occurred without convulsions. Thought to be asleep but could not be roused. Blood sugar 35 mg.%. Adrenalin 5 ml. of 1/1,000 sol. revived patient within ten minutes. This child has periodic spontaneous hypoglycaemic reactions often associated with vomiting, but no definite convulsions. Present condition satisfactory. Attacks only occasional. Diurnal variation showed minimal readings of 45 mg.%. Attacks very much less frequent. No clinical evidence of any visceral abnormality. Parents healthy. Other children in family healthy.

CASE III.—R. H. Spontaneous hypoglycaemia. Nutritional history normal. At the age of 3 years found in coma one morning. Clinical examination negative apart from toneless muscles, rapid feeble pulse. Became rapidly worse and appeared to be on the verge of death with breathing feeble and shallow. Blood sugar 26 mg.%. C.S.F. sugar 12 mg.%. Intravenous glucose given and 5 ml. of adrenalin which caused rapid improvement. Intravenous discontinued and child took food well for a time, and then refused entirely; blood sugar fluctuated at low levels. Insulin depression curve showed minimal reading of 47 mg. Was put on full diet and discharged home as satisfactory. Nine months later the boy was brought, in coma, to the Casualty Department. Two and a half ounces of glucose in water were passed into the stomach and in ten minutes consciousness was regained. No further attacks have occurred and the boy seems to have maintained improvement on a diet rich in fat and poor in carbohydrate. Present diurnal blood-sugar readings normal.

CASE IV.—P. M. I. Epilepsy with associated hypoglycaemia. Well until aged 10 years when menstruation commenced and slight convulsions synchronously. Occasional but definite epileptiform attacks occurred just before a meal and all occurred a few days after the end of a menstrual period. General physique and mental level good. Minimal blood sugar and diurnal variation 50 grammes %. E.E.G. showed definitely abnormal reading which is referred to as being of diffuse type rather than local, and therefore is in accordance with diagnosis of idiopathic epilepsy aggravated by hypoglycaemia phases.

CASE V.—J. M. Pituitary cachexia, with increased insulin sensitivity. No hypoglycaemia symptoms. At the age of 8 appeared in a grossly emaciated condition with weakness and all the signs of pituitary insufficiency. Pathologist's examination showed a cyst of the pituitary gland. Diurnal variation of the blood sugar showed minimal reading of 45 mg.

CASE VI.—M. B. Anorexia nervosa. No hypoglycaemia. In contrast with the case of J. M., in this patient—although similarly and grossly wasted—diurnal variation showed normal readings, and at no time any hypoglycaemia.

The Treatment of Celiac Disease with Vitamin B Complex and Liver Extract

By ERIC C. ALLIBONE, M.D.

Ross (1936) showed that the administration of liver extracts improved the glucose tolerance in celiac disease. Anderson (1945) had noticed that giving a mixture of five of the vitamin B fractions improved the appetite in this condition. May, McCreary and Blackfan (1942) using both parenteral liver and vitamin B complex obtained rapid clinical improvement with a rise in the vitamin A absorption tests, the patients being kept on a normal diet. Paterson, Pierce and Peck (1944) using the same method as May *et al.* confirmed the clinical improvement in celiac disease but did not obtain such good results in the vitamin A and oral glucose tolerance tests.

This paper records the results of the cases of celiac disease treated in this hospital on the above lines. Thanks to the kindness of Professor Struthers of Montreal and Messrs. John Wyeth and Brothers Ltd., London, it was possible to get the same preparations as were used in America by May and his co-workers.

Method.—After the initial investigations, daily intramuscular injections of vitamin B (4 c.c.) alternating with liver extract (2 c.c.) were given. The duration of the course

Clinical Section

President—A. DICKSON WRIGHT, M.S., F.R.C.S.

[April 12, 1946]

Sarcoidosis.—K. N. V. PALMER, M.B. (for Dr. G. E. BEAUMONT).

F. N., housewife, aged 40. Married, 3 children, aged 14, 10 and 6, all well.

Family history.—Mother died aged 55 of carcinoma of the womb. Nothing else relevant. No contact with pulmonary tuberculosis. Salivary glands never enlarged.

History.—Right pneumonia at the age of 9 years. Six years ago sudden onset of painful swelling and redness of both cheeks and nose. Radiotherapy in 1944; condition improved slightly. Soon after the face began to swell. Left index finger swollen and painful; amputated 22.3.45. Painful ulcer, soft palate, cleared up with sulphamezathine locally. In 1945 left great toe became painful and swollen; aching pain in shoulder, elbow-joints and back. Lassitude for the past three years. Cough for the past six years; brings up 1 oz. of non-offensive sputum; has never coughed blood.

The eyesight has been getting poor for the past six years. Mistiness and black moving spots. Eyeballs have never been sore. Right iritis and left cyclitis diagnosed 22.11.44.

On examination.—Fixed bluish induration over both cheeks and involving nose which is swollen and bulbous. Some scaling and dilated veins. Biopsy scar on each cheek. Patches of fixed purplish indurated erythema over lateral aspect of the arm. Some periarticular swelling of left wrist. Restriction of palmar flexion. Slight crepitus. Thickening and scaling of skin of palms; hands cyanosed. Swelling at proximal and intermediate phalanges of right middle finger, some limitation of movement. Not tender. Thickening and redness of patella. Swelling and purplish discoloration of right great toe. Scars of ulcers on legs (traumatic). Clubbing of fingers and toes. C.V.S.—N.A.D. Respiratory system: Medium moist crepitus which cleared on coughing heard at left mid-zone and right axilla. Some sibilant rhonchi at both bases.

Abdomen: Liver and spleen not palpable. Incisional hernia.

Right eye: Pupil small, edge blurred, irregular. Evidence of iritis. Reacts to light and constricts on convergence. Floaters in vitreous. Disc normal. **Left eye:** Pupil large, regular. Reacts to light and constricts on convergence. Floaters in vitreous. Some patchy haziness seen. Disc normal.

C.N.S.: N.A.D.

Report on X-ray of chest: Mottled opacities in both lung fields with some linear markings in mid-zone, compatible with sarcoidosis, and ? some dilated bronchi on the left. There is a cystic area in the right mid-finger (middle phalanx) and also an alteration of cancellous structure of the terminal phalanx of the first toes of both feet. The appearances are those of sarcoidosis.

Sputum (3 specimens).—No acid alcohol-fast organisms seen.

Serum calcium.—9.5 mg. per 100 ml.

SEPR.—CLIN. 1

Fat analysis of the stools determined before, after the parenteral and after the oral treatment showed on the average little change (Table II).

TABLE II.—FÆCAL FAT EXCRETION IN CÆLIAC DISEASE

	Daily output in grammes	Fat analysis, as a percentage of the dried faeces					No. of cases averaged
		Total fat	Unsapon- ified	Sapon- ified	Free	Neutral	
Before treatment	(3.1-15.4)	40.1 (28.4-52.1)	30.3 (16.4-40.8)	10.8 (1.4-21.0)	20.8 (0.5-29.0)	9.5 (1.2-25.0)	22
After parenteral therapy	5.85 (1.8-14.3)	30.8 (17.4-50.0)	27.4 (8.7-40.0)	11.0 (7.5-18.0)	10.0 (8.4-28.5)	8.4 (0.3-15.5)	21
After oral therapy	0.0 (1.5-11.5)	38.7 (18.5-55.4)	25.2 (11.4-40.5)	13.8 (1.0-25.0)	15.1 (4.4-28.8)	9.0 (3.2-10.8)	17

The intravenous glucose tolerance curves were raised on admission approaching normal as treatment proceeded (fig. 1). The oral glucose tolerance curves showed little change, averaging a maximum rise of less than 40 mg. per 100 c.c. in the blood sugar (fig. 2). An improvement in the intravenous but not in the oral glucose curves suggested the effect of therapy was on the utilization of sugar rather than on its absorption. Nevertheless the persistence of a slight elevation of the blood pyruvic acid level indicated a continued disturbance of carbohydrate metabolism (Table III).

TABLE III.—BIOCHEMICAL AND HÆMATOLOGICAL FINDINGS IN CÆLIAC DISEASE. (Average of 16 Cases.)

	Before treatment	After parenteral therapy	After oral therapy
Blood Pyruvic acid (mg.%)	1.12 (0.6-2.0)	1.30 (0.6-2.4)	1.38 (0.8-2.2)
Calcium (mg.%)	10.5 (8.3-11.5)	10.5 (9.6-12.4)	10.5 (9.0-13.0)
Phosphorus (mg.%)	4.0 (2.2-5.0)	4.8 (2.7-6.7)	5.1 (3.2-6.3)
Hb. (grammes%)	9.7 (7.4-12.4)		12.2 (8.0-13.0)
R.B.C. (millions)	4.62 (2.64-5.38)		4.54 (4.0-5.08)

The blood calcium and phosphorus averaged normal figures, though both tended to drop when the clinical condition deteriorated. In one case, not included in this series, values of 6.0 and 1.6 mg. per 100 c.c. respectively were obtained on more than one occasion in association with tetany. The presence of normal calcium and phosphorus levels did not guarantee the absence of osteoporosis and delay in ossification, though low levels were present in the more severe degrees of bone change (Table IV).

TABLE IV.—X-RAY CHANGES IN CÆLIAC DISEASE.

Before treatment	After treatment	No. of cases
Slight osteoporosis	Improved	2
Slight osteoporosis with slight rickets	Improved	1
Osteoporosis	Improved	3
Osteoporosis	Slightly improved	4
Osteoporosis	Not improved	5
Osteoporosis	Not improved with slight rickets	2

The hæmoglobin levels rose with treatment though transfusions were sometimes necessary in a crisis. In fact the blood as well as the whole clinical and metabolic picture was subject to considerable fluctuation. The rapidity with which the reception of the morning greeting would change from a smile to a frown reflected the lability of the patient's condition.

CONCLUSION

The administration of high doses of vitamin B and liver in cœliac disease ameliorates the strictness of the dietary treatment in the milder types. The more severe cases derive a less easily demonstrable benefit. From the data accumulated there is no evidence that this form of treatment is specific.

ACKNOWLEDGMENT

Thanks are due to Professor L. G. Parsons and Dr. E. M. Hickmans for their help in planning this study as well as for their criticism and advice.

Report on X-ray of chest: Mottled opacities in both lung fields with some linear markings in mid-zone, compatible with sarcoidosis, and ? some dilated bronchi on the left. There is a cystic area in the right mid-finger (middle phalanx) and also an alteration of cancellous structure of the terminal phalanx of the first toes of both feet. The appearances are those of sarcoidosis.

Sputum (3 specimens).—No acid alcohol-fast organisms seen.

Serum calcium.—9.5 mg. per 100 ml.

SEPT.—CLIN. 1

Plasma proteins.—Albumin 3.1 grammes, globulin 3.7 grammes, fibrinogen 0.39 grammes per 100 ml.

Blood-count.—Hb. 90% = 13.5 grammes%. Leucos. 10,300, neuos. 73%, lymphos. 20%, monos. 5%, cosinos. 2%.

Serum alkaline phosphatase 7.8 units; serum acid phosphatase 2.5 units.

Biopsy from cheek.—A heavily infected papillomatous lesion showing giant cells and endothelial cells. No tubercle bacilli seen. Appearances compatible with Bocck's sarcoid.

Mantoux 1 in 10,000 negative; 1 in 1,000 positive.

Dr. F. Parkes Weber emphasized the variety and striking character of the constituent features of this case of generalized Bocck-Schaumann sarcoidosis: (1) Hutchinson's "lupus-bernio" of the nose and rosaceous type of facial sarcoidosis; (2) indurated erythema of arm, &c.; (3) involvement of the respiratory system; (4) involvement of bones and bone-marrow, as in the cases so well demonstrated by Schaumann; (5) evidence of iritis and cyclitis, though without the parotid swelling of the so-called uveo-parotid syndrome (Hcerfordt).

Dr. H. S. Stannus asked whether treatment by very large doses of calciferol as in lupus had ever been tried.

Dr. Herbert Levy said that arsenic and oleum morrhuate had been recommended for the treatment of sarcoidosis (the former by Snapper) but judgment of their effect is difficult as spontaneous recovery is so frequent. Kveim's report of a specific cutaneous reaction for sarcoidosis (*A. Kveim, Nord. Med.*, 1941, 9, 169; *N. Danbolt and R. W. Nilssen, Acta dermat. vener.*, 1945, 25, 489) where an extract from an involved lymph node is used as antigen would seem to deserve attention.

Lipodystrophy.—**J. S. Richardson, M.D.** (Medical Unit, St. Thomas's Hospital).

E. Y., married woman, aged 53. Four children.

Normal and slim in appearance up to the age of 40, when she was ill for six months and had pleurisy with effusion. Immediately after this she noticed that her face was getting thinner, and one year later she began to put on weight over her hips and buttocks. Periods stopped two years ago, having been regular and normal from age of 13; still gets flushes; since 1942 has felt continuously tired with frontal headaches. Pain in legs, by day and night, for four months.

No family history of endocrine disorder or of abnormal fat distribution.

On examination.—Height 5 ft. Lower measurement 28½ in. Span 58¾ in. Abdomen lower costal margin 32 in. Buttocks at trochanters 47 in. Weight 11 st. 6 lb. Complete absence of subcutaneous fatty tissue over the face. Well-developed muscles of arms and shoulder girdles, which stand out owing to loss of subcutaneous fat. Skin normal without pigmentation. Breasts have lost almost all fatty tissue; lipoma at right anterior axillary fold. Abdomen covered by pendulous apron of fat; buttocks gross, irregular deposition of fat. Legs show pitting oedema with varicose veins and eczema. Muscle power, cutaneous sensation, skin and tendon reflexes normal. B.P. 120/80.

X-ray of chest and stereo X-ray of skull: N.A.D.

X-ray of lumbar spine shows marked osteoarthritis.

Urine: Sp. gr. 1022, acid—no abnormal constituents. 17-ketosteroids 7.6 mg. per 24 hours. B.M.R. minus 7. Blood: W.R. negative. Sugar (midday) 0.069%. Sugar tolerance curve normal. Calcium 8.2 mg., inorganic phosphate 3.1 mg., sodium 310 mg., chlorides 614 mg. per 100 c.c.

Blood-count.—R.B.C. 5,000,000; Hb. 100%; C.I. .99. W.B.C. 9,400 (polys. 49%, leucos. 34%, monos. 10%, basos. 1%, cosinos. 6%).

Fat tolerance test (G. Popják).—Plasma lipids (mg./100 ml.) before and after ingestion of 80 grammes of butter fat. Test performed fifteen hours after the last meal.

Time after fatty meal hour	Non-phospho-lipid fatty acids	Neutral fat	Phospho-lipid	Cholesterol		Total
				Free	Ester	
0	391	266	280	58	190	248
1½	386	267	280	57	182	239
3½	549	429	298	61	194	255
5½	655	537	308	66	199	265
8½	615	495	322	66	199	265

Dr. F. Parkes Weber said that a feature in the present case was the relatively late onset of the symptoms—nearer to the climacteric period than to the onset of puberty. The excessive accumulation of subcutaneous fat in the lower part of the trunk and thighs approached the type specially described by Laignel-Lavastine and Viard; it did not occur in most of the rare cases in males. Altogether, one might liken typical "lipodystrophia progressiva" in females to a caricature of the change which normally takes place in many middle-aged women when they "spread out" in the lower part of the trunk and get thinner in the face (cf. F. P. Weber, *Lipodystrophia Progressiva*, London, 1918, pp. 10–12).

[May 10, 1946]

Case for Diagnosis. ? Congenital Heart Disease with Atrial Septal Defect: ? Mitral Stenosis.
—COURTENAY EVANS, M.D.

Miss G. C., aged 43.

History.—Tired and short of breath. Heart found to be enlarged and abnormal a year ago. No rheumatic fever or illnesses in childhood.

On examination.—Heart enlarged. Rhythm regular. No congestive failure. Apex beat in sixth space, just outside mid-clavicular line. Loud systolic murmur at apex, conducted outwards. First sound loud, slight suggestion of presystolic murmur. Systolic murmur also heard over second and third interspaces (left). B.P. 140/90.

X-ray examination.—Heart: Considerable enlargement of pulmonary artery and its branches, pulsation in right and left pulmonary artery branches. Right ventricle enlarged. Barium swallow does not show any dilatation of left auricle. Electrocardiogram: Right axis deviation with widening of Q.R.S. to 0.08 sec. T wave inversion in lead 3 and also in chest lead C.R.I. Early right bundle branch block.

W.R. negative.

Dr. A. Schott agreed that this was a case of interauricular septal defect with mitral stenosis, i.e. Lutembacher's syndrome. Mitral valvular disease alone could be excluded, as in that case the patient would have been far more seriously ill; moreover, enlargement of the left auricle, for which there was no radiological evidence in this case, would have to be expected, whereas such enlargement is frequently absent in patients in whom mitral stenosis is associated with interauricular septal defect. Eisenmenger's syndrome, i.e. interventricular septal defect, right-sided enlargement, dextroposition of the aorta and dilatation of the pulmonary artery was unlikely as this condition is very rare as compared with the relative frequency of Lutembacher's syndrome and cyanosis seems to be more marked and to occur earlier in Eisenmenger's syndrome than was observed in this case.

Idiopathic dilatation of the pulmonary artery cannot be differentiated radiologically from interauricular septal defect, but its association with mitral stenosis has not been observed; moreover, this condition also is very rare as compared with Lutembacher's syndrome.

Cirrhosis and Ascites (Treated by Omentopexy Twelve Years ago after Investigation by Thorium Dioxide).—ARTHUR E. PORRITT, C.B.E., F.R.C.S.

Mrs. E. L., aged 69.

First referred to St. Mary's Hospital in October 1934 having previously attended another hospital since July of that year. She was originally diagnosed as a large ovarian cyst. Laparotomy (August 1934) showed nothing abnormal in the pelvis, a marked liver enlargement and massive ascites—2½ gals. of fluid being aspirated on this occasion. The hepatic masses chiefly in the left lobe were described as "lobular rather than nodular and not umbilicated". No primary growth was discovered.

In October 1934 ascites was again found and on admission the umbilicus was everted by distension, and shifting dullness and a fluid thrill were present. Temperature, pulse and respiration were normal, but the urine contained blood and pus and a well-marked uterine prolapse was present. The patient had had three healthy children and a straightforward menopause eight years previously.

The abdomen was tapped, 5 pints of pale yellow fluid being removed which did not clot on standing, contained 800 cells per c.c., chiefly endothelial and lymphocytes.

75 c.c. of "thorotrast" (thorium dioxide) were injected intravenously in 3 doses of 25 c.c., a two-day interval being left between each injection. Reactions were minimal and two days later a good picture of the liver and spleen was taken, the shadow of the latter being considerably denser (Dr. Gage and Dr. Rohan Williams). Appearances suggested cirrhosis and the presence of a Reidel's lobe.

A week later a mid-line supra-umbilical laparotomy was performed, the peritoneal surfaces of liver and spleen roughened to oozing point with dry gauze and the omentum brought through and implanted in the layers of the anterior abdominal wall (Talma Morrison operation).

The blood picture was: R.B.C. 4,800,000; Hb 88%; C.I. 0.9. W.B.C. 5,500.

Two weeks later, 7 pints were aspirated from the abdomen and the patient was discharged one month after the omentopexy. One month later, 4 pints of ascitic fluid were removed.

She was kept under frequent observation until June 1939. At no time did the hæmoglobin fall below 72%, the R.B.C. below 4,350,000 and the W.B.C. below 5,000.

Plasma proteins.—Albumin 3.1 grammes, globulin 3.7 grammes, fibrinogen 0.39 grammes per 100 ml.

Blood-count.—Hb. 90% = 13.5 grammes%. Leucos. 10,300, neuros. 73%, lymphos. 20%, monos. 5%, eosinos. 2%.

Serum alkaline phosphatase 7.8 units; serum acid phosphatase 2.5 units.

Biopsy from cheek.—A heavily infected papillomatous lesion showing giant cells and endothelial cells. No tubercle bacilli seen. Appearances compatible with Boeck's sarcoid.

Mantoux 1 in 10,000 negative; 1 in 1,000 positive.

Dr. F. Parkes Weber emphasized the variety and striking character of the constituent features of this case of generalized Boeck-Schaumann sarcoidosis: (1) Hutchinson's "lupus-panis" of the nose and rosaceous type of facial sarcoidosis; (2) indurated erythema of arm, &c.; (3) involvement of the respiratory system; (4) involvement of bones and bone-marrow, as in the cases so well demonstrated by Schaumann; (5) evidence of iritis and cyclitis, though without the parotid swelling of the so-called uveo-parotid syndrome (Heerfordt).

Dr. H. S. Stannus asked whether treatment by very large doses of calciferol as in lupus had ever been tried.

Dr. Herbert Levy said that arsenic and oleum morrhuate had been recommended for the treatment of sarcoidosis (the former by Snapper) but judgment of their effect is difficult as spontaneous recovery is so frequent. Kveim's report of a specific cutaneous reaction for sarcoidosis (A. Kveim, *Nord. Med.*, 1941, 9, 169; N. Danbolt and R. W. Nilssen, *Acta dermat. vener.*, 1945, 25, 489) where an extract from an involved lymph node is used as antigen would seem to deserve attention.

Lipodystrophy.—J. S. RICHARDSON, M.D. (Medical Unit, St. Thomas's Hospital).

E. Y., married woman, aged 53. Four children.

Normal and slim in appearance up to the age of 40, when she was ill for six months and had pleurisy with effusion. Immediately after this she noticed that her face was getting thinner, and one year later she began to put on weight over her hips and buttocks. Periods stopped two years ago, having been regular and normal from age of 13; still gets flushes; since 1942 has felt continuously tired with frontal headaches. Pain in legs, by day and night, for four months.

No family history of endocrine disorder or of abnormal fat distribution.

On examination.—Height 5 ft. Lower measurement 28½ in. Span 58¾ in. Abdomen lower costal margin 32 in. Buttocks at trochanters 47 in. Weight 11 st. 6 lb. Complete absence of subcutaneous fatty tissue over the face. Well-developed muscles of arms and shoulder girdles, which stand out owing to loss of subcutaneous fat. Skin normal without pigmentation. Breasts have lost almost all fatty tissue; lipoma at right anterior axillary fold. Abdomen covered by pendulous apron of fat; buttocks gross, irregular deposition of fat. Legs show pitting œdema with varicose veins and eczema. Muscle power, cutaneous sensation, skin and tendon reflexes normal. B.P. 120/80.

X-ray of chest and stereo X-ray of skull: N.A.D.

X-ray of lumbar spine shows marked osteoarthritis.

Urine: Sp. gr. 1022, acid—no abnormal constituents. 17-ketosteroids 7.6 mg. per 24 hours. B.M.R. minus 7. Blood: W.R. negative. Sugar (midday) 0.069%. Sugar tolerance curve normal. Calcium 8.2 mg., inorganic phosphate 3.1 mg., sodium 310 mg., chlorides 614 mg. per 100 c.c.

Dr. F. Parkes Weber said that a feature in the present case was the relatively late onset of the symptoms—nearer to the climacteric period than to the onset of puberty. The excessive accumulation of subcutaneous fat in the lower part of the trunk and thighs approached the type specially described by Laignel-Lavastine and Viard; it did not occur in most of the rare cases in males. Altogether, one might liken typical "lipodystrophia progressiva" in females to a caricature of the change which normally takes place in many middle-aged women when they "spread out" in the lower part of the trunk and get thinner in the face (cf. F. P. Weber, *Lipodystrophia Progressiva*, London, 1918, pp. 10–12).

of constant iron treatment a count on April 30 showed: R.B.C. 4,010,000; Hb. 68%. Intermittently, there was sinus formation to the skin over the horizontal ramus of the right mandible.

Comment.—"Pellagra is certainly a rare disease in Great Britain" (H. S. Stannus and C. R. Gibson, 1934, *Quart. J. Med.*, N.S. 20, 211): the second World War has not made it less rare in Great Britain. Working for the greater part of the war in hospitals serving particularly poor districts of London where at least 4 to 5 cases of frank scurvy came under my charge per year, I saw two cases of an acute hallucinatory psychosis in elderly afebrile patients who lost their psychotic symptoms within twenty-four to forty-eight hours of parenteral nicotinamide treatment (cf. B. Gottlieb, 1944, *Brit. med. J.* (i), 392) but neither of them had any skin lesions. This patient is the first I have seen during that time showing the full picture of pellagra. Unfortunately, it was not possible to obtain a reliable dietary history, but undoubtedly the carcinoma of the mouth from which he suffered in 1944 and 1945 will have changed his dietary habits. The skin lesions included areas which had never been exposed to sunlight.

Dr. H. S. Stannus: Dr. Levy's case of pellagra illustrates very well so many of the symptoms met with in that disease and at the same time serves as a basis for discussion of some of the fallacious observations often made concerning the signs and symptoms which may occur. It is only possible to refer to a few points.

The extension of the dermatitis to the dorsa of the toes is well shown. It would be interesting to learn whether the toes had been exposed to sunshine preceding the appearance of the exanthem. The fact is, as I first pointed out many years ago, that the dermal manifestations tend to appear in any area of skin in which as the result of past trauma of any kind, including equally sunshine and chapping due to cold, the capillaries have suffered permanent damage. The almost universal extension of the dermatitis to the flexor aspects of the wrists also seen in this case can only thus be explained.

The oil-silk or lacquered appearance of the skin of the shins in this man is a condition rather characteristic of chronic pellagra. It sometimes shows cracking, giving a condition often referred to as "crazy-pavement" skin.

I will only refer to one other point—diarrhoea; this is by no means a constant symptom as has often been asserted, in many cases constipation is present. And a word of warning—the administration of a purge may then set up an intractable diarrhoea. In regard to treatment by nicotinic acid, I think it might be advisable to give large doses, 500 mg. per day in divided doses of 100 mg. each.

Hypertension treated by Arteriovenous Anastomosis.—A. DICKSON WRIGHT, M.S., F.R.C.S.

G. B., aged 40, seen in February 1946 with advanced malignant hypertension. His systolic blood-pressure varied from 250-300 and diastolic from 150-170. His main symptoms were bad nightmares, claudication in the legs and rapid deterioration of vision.

On examination.—There was extensive retinal damage from hæmorrhage and exudation and papilloedema. Pulsus alternans was present with 50 mm. difference between alternate pulses. The blood urea was 120 mg. per 100 c.c. and urine contained much albumen. Anastomosis between the left external carotid and external jugular was made on February 26, and two weeks later his blood-pressure was 175/115.

On March 29 he reported himself as "feeling better than for a long time". His complexion and aspect were better and he was sleeping well and could read the paper, and although he could hear the murmur it did not keep him awake. The pulsus alternans was still present with 10 mm. difference between beats and his blood-pressure was 210/115. The blood urea was now only 32 mg. and albumen was only slight. On closing the fistula with finger pressure the systolic rose 40, the diastolic pressure 50 points. The operation was done to provide a safety valve to preserve the vision in a hopeless case of hypertension, the improvements in other directions were unexpected and would repay investigation.

Lymphadenoma.—By LEO RAU, M.D., M.R.C.P.

Female, aged 24. Was first seen in May 1941, after she had been ill for six months. Her complaints were backache, vomiting without any reason or warning, hoarseness, loss of weight from 10 st. 7 lb. to 8 st. Her periods had always been normal. On examination—typical right Horner's syndrome, palsy of right recurrent nerve, typical lymph glands in right neck. Spleen and liver not palpable. Diagnosis: Lymphadenoma.

Investigations.—Secondary anæmia, marked anisocytosis and microcytosis. Differential leucocyte count: Polys. 83%, lymphos. 7%, monos. 9% and eosinos. 1%. Radiograph of chest—large shadows in both mediastina, typical of Hodgkin's disease (see fig. 1).

Dr. F. M. Allchin, at Westminster Hospital, undertook treatment. Between May 1941 and June 1944 she received six courses of deep X-ray therapy as an out-patient. The first

She was not seen again until March 1946—eleven and a half years after the omentopexy and the injection of thorotrast. No tapping had been done since the two immediate post-operative ones described above. She was in excellent health and had been so throughout the period. Her blood examination now showed Hb. of 76% and R.B.C. count of 4,500,000. An X-ray examination had not yet been possible. A W.R. taken during the war was ++, and the Kahn +++, but it should be noted that no anti-specific therapy has been given at any time.

The interest of the case lies in the completely successful result of an omentopexy for the ascites and what is presumably a specific cirrhosis and in the fact that a very enlarged liver and spleen filled with thorium dioxide for practically twelve years has to date given no ill-effects either on the blood picture or elsewhere.

Pellagra.—HERBERT LEVY, M.D., M.R.C.P.

James J., aged 70.

January 1945: "Extensive carcinoma involving the right side of the floor of the mouth, cheek, alveolus and ulcerating through the skin to the right submaxillary region." Treated as out-patient at London Hospital with deep X-rays (4,500 r in twenty-eight days). Good response to treatment. "He has not attended the Department since January 1946 when his mental condition seemed to have deteriorated and his wife stated that he was in a continuous drowsy condition." (Extract from notes supplied by Dr. W. Shanks.)

Admitted Bethnal Green Hospital March 31, 1946, on account of pain in right posterior chest wall following a fall the previous day.

On examination.—Lying perfectly listless with dull lifeless stare, continuously rubbing his face and hands. Answers question as to site of pain only after considerable delay; does not answer any other simple questions.

Dermatitis of face and part of neck with considerable infiltration of skin, the colour being nearly that of an erysipelas. Chronic dermatitis with lichenification of back of hands and distal forearms. Alligator-like hyperkeratosis of skin (dark brown-blackish) over back of feet and toes up to distal fourth of legs; the hyperkeratotic tissue can be fairly easily separated from the underlying dermis, leaving a raw surface. Patch of chronic dermatitis at inner side of left thigh. Pigmentary marmoration *ab igne* over parts of lower limbs. (The skin lesions had been noticed by his wife for "some months" and the facial eruption had some four months ago been diagnosed, and treated, as erysipelas.) Scratch-marks on forearms and legs with areas of secondary infection.

Marked pallor of visible mucous membranes but no other abnormalities of oral mucous membrane, angles of mouth, tongue, or anal sphincter. Small patches of pigmentation on inner and outer parts of bulbar conjunctivæ; no circumcorneal injection to naked-eye inspection.

Gross defect of right mandible with localized dimpling of soft tissues but no sinus opening. No significant lymph-node enlargement at neck. No reduction in amount of subcutaneous fat. Muscle tone within normal limits for age-group. Deep and plantar reflexes normal. Localized tenderness over seventh right rib in mid-scapular line. Liver reaches to 1 in. below costal margin. No other relevant findings.

Blood examination (Dr. J. M. Alston).—3.4.46: R.B.C. 3,740,000; Hb. 66%. W.B.C. 6,900 (neutr. polys. 70%, eosino. polys. 4%, lymphos. 26%).

10.4.46: Skiagrams: No evidence of metastases in pelvis or ribs; right lower jaw shows large area of destruction with fracture.

15.4.46: Serum albumin: 3.9 grammes %; serum globulin 3.6 grammes %; serum Ca: 11 mg. %; inorganic P. 4.5 mg. %; acid phosphatase: 1.7, and alkaline phosphatase 9 units.

6.5.46: Fractional test meal: Normal acidity.

Treatment with nicotinamide, crude liver extract, marmite, and ferrous sulphate was started on admission (nicotinamide 300 mg. on first day, 200 mg. daily on next two, and 150 mg. on following ten days subcutaneously). The angry redness and a good deal of the inflammatory infiltration of the facial eruption disappeared within forty-eight hours; the hyperkeratotic crust on the feet had entirely peeled off after about three weeks, leaving a skin with fairly sharply limited hyperpigmentation and some lichenification as visible still now, five weeks after admission.

The extreme lethargy had improved slightly but noticeably about four to five days after admission; for the first two weeks patient had to be fed. For the last two weeks he has been up and about, feeding himself but still showing very considerable impairment of cerebration and never talking spontaneously. His stools were normal throughout in number, consistency, and colour and there is no history of previous diarrhoea. In spite

of constant iron treatment a count on April 30 showed: R.B.C. 4,010,000; Hb. 68%. Intermittently, there was sinus formation to the skin over the horizontal ramus of the right mandible.

Comment.—"Pellagra is certainly a rare disease in Great Britain" (H. S. Stannus and C. R. Gibson, 1934, *Quart. J. Med.*, N.S. 10, 211): the second World War has not made it less rare in Great Britain. Working for the greater part of the war in hospitals serving particularly poor districts of London where at least 4 to 5 cases of frank scurvy came under my charge per year, I saw two cases of an acute hallucinatory psychosis in elderly afebrile patients who lost their psychotic symptoms within twenty-four to forty-eight hours of parenteral nicotinamide treatment (cf. B. Gottlieb, 1944, *Brit. med. J.* (i), 392) but neither of them had any skin lesions. This patient is the first I have seen during that time showing the full picture of pellagra. Unfortunately, it was not possible to obtain a reliable dietary history, but undoubtedly the carcinoma of the mouth from which he suffered in 1944 and 1945 will have changed his dietary habits. The skin lesions included areas which had never been exposed to sunlight.

Dr. H. S. Stannus: Dr. Levy's case of pellagra illustrates very well so many of the symptoms met with in that disease and at the same time serves as a basis for discussion of some of the fallacious observations often made concerning the signs and symptoms which may occur. It is only possible to refer to a few points.

Gross defect of right mandible with localized dimpling of soft tissues but no sinus opening. No significant lymph-node enlargement at neck. No reduction in amount of subcutaneous fat. Muscle tone within normal limits for age-group. Deep and plantar reflexes normal. Localized tenderness over seventh right rib in mid-scapular line. Liver reaches to 1 in. below costal margin. No other relevant findings.

Blood examination (Dr. J. M. Alston).—3.4.46: R.B.C. 3,740,000; Hb. 66%. W.B.C. 6,900 (neutr. polys. 70%, eosino. polys. 4%, lymphos. 26%).

10.4.46: Skiagrams: No evidence of metastases in pelvis or ribs; right lower jaw shows large area of destruction with fracture.

15.4.46: Serum albumin: 3.9 grammes %; serum globulin 3.6 grammes %; serum Ca: 11 mg.%; inorganic P. 4.5 mg.%; acid phosphatase: 1.7, and alkaline phosphatase 9 units.

6.5.46: Fractional test meal: Normal acidity.

Treatment with nicotinamide, crude liver extract, marmite, and ferrous sulphate was started on admission (nicotinamide 300 mg. on first day, 200 mg. daily on next two, and 150 mg. on following ten days subcutaneously). The angry redness and a good deal of the inflammatory infiltration of the facial eruption disappeared within forty-eight hours; the hyperkeratotic crust on the feet had entirely peeled off after about three weeks, leaving a skin with fairly sharply limited hyperpigmentation and some lichenification as visible still now, five weeks after admission.

The extreme lethargy had improved slightly but noticeably about four to five days after admission; for the first two weeks patient had to be fed. For the last two weeks he has been up and about, feeding himself but still showing very considerable impairment of cerebration and never talking spontaneously. His stools were normal throughout in number, consistency, and colour and there is no history of previous diarrhoea. In spite

Repeated blood-counts never revealed any abnormality with the exception of a hypochromic anæmia and lymphopenia.

With the X-ray treatment she has been kept sufficiently fit to carry on her work efficiently. She is one of the few instances of this unpleasant disease that has benefited by radiation therapy.

Jejuno-gastric Intussusception.—W. H. J. WESTON, F.R.C.S., introduced by Ivor LEWIS, M.S.

R. C., male, aged 43, milk roundsman, admitted to the North Middlesex County Hospital March 27, 1946, after two and a half days of violent abdominal pain. The pain woke him and immediately he vomited clear yellow fluid. Eighteen years previously he had had a gastrojejunostomy performed.

The pain began in the left hypochondrium and was said to be a "steady" pain. After the pain had begun he passed neither fæces nor flatus. He was a thin man with sunken eyes, a dry tongue, and washerwoman's fingers. The vomit was reddish-brown.

A vague tender mass could be felt in the left hypochondrium and the iliac fossæ were curiously empty. Violent peristaltic sounds could be heard.

A diagnosis of high intestinal obstruction was made, almost certainly due to stoma intussusception. An upright X-ray of the abdomen showed, not the large gas-dilated fundus of stomach and fluid levels of other acute intestinal obstruction cases, but a stomach filled by a mass of intussuscepted gut.

At operation (Mr. Ivor Lewis) an intussusception of the efferent limb of the gastrojejunostomy into the stomach was found. The loop was reduced by pressure from above and gentle traction.

After three days' continuous gastric aspiration and intravenous fluids he made a good recovery.

One month after operation a barium meal showed a normally functioning gastrojejunostomy.

Hand-Schüller-Christian Syndrome.—M. B. MATTHEWS, M.B., M.R.C.P.

H. R., an insurance agent, aged 47, was referred by Dr. Smiles of Wokingham to St. Thomas's Hospital in May 1946 with a diagnosis of Hand-Schüller-Christian syndrome. His chief complaint was dizziness for one month. There was nothing relevant in his past history before 1928. He stated that his maternal grandfather had died of the "drinking diabetes".

In 1928 he first noticed that he had "lost his saliva"; since then his mouth has been persistently dry and he has been accustomed to eat fruit with bread and butter so as to make mastication easier. There has been no polyuria. In 1933 all his teeth were extracted for pyorrhœa and for the following four years he wore dentures. In 1936 he first noticed a swelling on the tip of the mandible. This made his dentures uncomfortable and early in 1937 he attended the Royal Berkshire Hospital, Reading, where an X-ray showed a cavity in the mandible. Histological examination of the tissue obtained from this cavity showed "large spheroidal cells with oval nuclei, infiltrated with a large number of wandering cells, mainly polymorphs". The pathologist was not prepared to say whether the process was neoplastic. In 1936 an ulcer of the rectum which was thought clinically to be tuberculosis was excised locally; histological examination showed no evidence of tuberculosis. In 1938 his wife first noticed that the patient had exophthalmos. Also in this year he had persistent root pains at about the level of D.6 worse in the morning, better on movement and relieved by aspirin four-hourly. After six months the pain gradually improved. The mandible was irradiated in this year as small pieces of bone were discharging into the mouth. After six months the discharge ceased but the mandible has become progressively smaller. Coincidentally a swelling about the size of a walnut appeared in the skin over the right maxilla. There is no report available about this, but it disappeared following deep X-ray therapy. For the last three years he has noticed that his enunciation has become difficult. Since then, until recently, his only symptoms have been a non-productive cough, lassitude and persistent dryness of the mouth.

In April of this year he first noticed dizziness and deafness of the left ear, without true vertigo, making walking difficult. He still has slight dizziness in the morning. There are no other abnormal symptoms and he has lost no weight.

On examination.—Normally-developed adult male, weighing 128¾ lb. Marked bilateral exophthalmos with limitation of ocular movements in all directions. The mandible is very wasted, producing a shrew mouse profile; the soft tissues are preserved. There is no anæmia or lymphatic glandular enlargement. Apart from slight slow nystagmus to the

treatment was to the chest, which received 3,600 r. After this, the Horner's syndrome and the paralysis of the recurrent nerve disappeared. She remained well until November 1942, and in December 1942 the left supraclavicular and left axilla were treated by deep X-ray therapy. Each area received 1,000 r. She remained well until July 1943 when enlarged glands on the left side of her neck were treated, and a dose of 1,800 r was given. In October 1943, she complained of pain in the chest. Radiographs showed congestion of the right base, and some irregular shadows just below the interlobar line. She was given a further course of deep X-ray therapy, 3,400 r skin dose to the chest. She remained well, but in March 1944 there was infiltration of both bases, and a further skin dose of 2,200 r was given to the chest. In June 1944, glands of the left axilla became enlarged and 2,000 r were given. In January 1945 she complained of some pain in the right side of the chest and pyrexia. There was loss of weight. A further course of deep X-ray therapy, 2,000 r to the anterior superior mediastinum and again 2,700 r to the left base was given. In June 1945 she reported feeling very weak, was unable to walk and there was a mass in the abdomen. She was treated through one port, 10 x 8 cm. and a skin dose of 1,500 r was given. She improved rapidly and remained well until December 1945. She developed a troublesome cough, pain in the left side of the abdomen. X-rays showed no obvious glandular enlargement but extensive bilateral pulmonary involvement. 3.1.46: Hb, 66%; W.B.C. 11,600 (polys. 9,744 per c.mm., lymphos. 812 per c.mm.). She improved rapidly following deep X-ray therapy, 1,200 r anteriorly, and 1,300 r posteriorly to the right mid-zone of the chest. She has remained well since then.

For the last fifteen months she has been working as a cashier in one of the big stores and feels fit. Her weight (May 1946) is 7 st. 6½ lb. She looks well. Spleen and liver are not palpable. There are a few glands palpable in the left side of the neck and left groin, supra-inguinal. The X-ray of the chest shows no obvious glandular enlargement but some pulmonary involvement: right pulmonary infiltration and collapse of left lower lobe.

Comment.—Although there has been no biopsy of a gland, there cannot be much doubt that this is a case of lymphadenoma. Clinically, the recurrences of palpable glands in the different regions and the original radiogram of the chest are typical of the disease. The X-ray appearances of the chest during the five years may not be specific, but the disappearance of the manifestations after X-ray treatment is, I believe, typical of the disease. The follow-up of the radiographs of the chest is most instructive, as at times the films reveal pathology which might be explained as areas of collapse due to regional lymphadenomatous lymphangitis, and others show larger nodules infiltrating the lung tissue.

Without the follow-up many of the radiographs show pathology which could be mistaken for pulmonary tuberculosis, or Boeck's sarcoid, or Loeffler's syndrome, such as has been shown by Elkeles and others in this Section. [See figs. 1 and 2.]

FIG. 1. 9.6.41.
Enlargement of mediastinal glands.

FIG. 2. 30.5.45.
Infiltration of right mid-zone and hilar glands; further
bilateral infiltration of lower lobes.

A Method of Treating Bennett's Fracture

By V. H. ELLIS, F.R.C.S.

BENNETT'S fracture, dislocation of the first metacarpal, is a comparatively common injury. A bad anatomical result of treatment gives a bad functional end result. Reduction is not difficult as a rule, but the maintenance of position is the chief problem. The usual method of fixation advocated is by traction on the thumb with joints extended, together with plaster fixation with close moulding round the base of the metacarpal.

FIG. 1.

The method I have devised involves the exposure of the outer aspect of the carpo-metacarpal joint, reduction of the fracture and its maintenance in position by two short pegs or nails introduced obliquely into the trapezium forming a shelf so that redislocation cannot occur (fig. 1). The pegs are inserted in drill holes about one-third of an inch deep and project sufficiently to support the base of the metacarpal. The skin is sutured over the pegs and the thumb and wrist immobilized in a scaphoid type of plaster which allows good use of the hand.

Immobilization is continued for six weeks. Then the plaster is removed and the pegs taken out at a further minor operation.

The five-year results in two cases are very good, and in six or seven others there is no reason to expect any permanent disability.

A Method of Treating Fractures of the Neck of the Talus

By V. H. ELLIS, F.R.C.S.

Fracture of the neck of the talar bone with displacement is usually associated with subtaloid dislocation. I am not concerned with the variety in which the body of the talus is displaced backwards out of the ankle mortice.

Reduction of fracture of the neck of the talus is usually easy by manipulation into full plantar flexion and eversion. The usual practice is to immobilize the limb in this position.

The surgeon is now in a dilemma. Prolonged immobilization in full equinus may lead to a fixed deformity. Placing the foot at a right angle too early causes redisplacement of the fracture.

In my experience a fixed equinus may develop in seven to eight weeks, especially in older patients. I have overcome this difficulty by introducing a quarter-inch graft from the tibia into the long axis of the talus from behind, after reduction has been achieved by manipulation. This fixes the fracture sufficiently to allow immediate immobilization of the ankle at 90 degrees.

With the patient prone and the knee flexed a graft of $4\frac{1}{2}$ cm. long and quarter of an inch wide is taken from the tibia. The knee is now extended and the fracture reduced by manipulation.

right there are no abnormal signs in the central nervous system. Air entry is diminished at the left apex with post-tussic crepitations at the right base. The cardiovascular system is normal; the blood-pressure 140/90. There are no abnormalities in the gastro-intestinal tract. The urine contained a trace of albumin on one occasion but no Bence-Jones proteose. Apart from wax in the left ear, no abnormality could be found in the ears, nose or throat. There is a marked kyphosis of the level of about C.7. There is no bone tenderness in the spine, nor palpable abnormality in the skull or long bones. There are two small yellow intracutaneous plaques on the outer sides of each eye, considered by Dr. Dowling to be xanthomata.

Investigations.—

	Fasting plasma lipids	mg. 100/ml.	Serum calcium	..	10 mg.%
Non-phospholipid fatty acids	..	232	Inorganic phosphate	..	4 mg.%
Neutral fat	..	126	Alkaline phosphatase	..	4 units
Phospholipids	..	222	Blood-count.—		
Free cholesterol	..	55	R.B.C.	..	5,500,000 per c.mm.
Ester cholesterol	..	155	Hb.	..	68%
Total cholesterol	..	210	C.I.	..	0.6
			Leucocytes	..	21,000 per c.mm.
			(polys. 87%, lymphos. 4%, monos. 7%, eosinos. 2%).		

Sternal marrow normal. Blood Wassermann reaction negative. Blood sedimentation rate—49 mm. in 1 hour.

Glucose Tolerance Test (50 oz. glucose orally 9.30 a.m.)

Time hrs.	Blood sugar mg.%	Urine sugar
0	150	
1	160	
1½	192	
2	209	Nil
2½	213	
3	228	Nil
	203	Nil

Radiographs.—In the skull there are extensive changes of xanthomatosis throughout with involvement of left mastoid, right maxilla and whole mandible. The orbital fissures are not distinguishable. The spine shows collapse of D.6. There is a uniformly dilated uncoiled aortic arch with reticulation of both lung fields, chiefly of the lower lobes. In the pelvis there are extensive changes with rarefaction and sclerosis. The right femur shows bone sclerosis and thickening of periosteum. The appearance is similar to that of Paget's disease. The left and right radii show areas of slight rarefaction.

While in hospital he has run a slight intermittent fever up to 99.6°. The specific gravity of the urine varies between 1010 and 1015; the daily output is normal.

The patient was unwilling to undergo plastic reconstruction of the jaw. As he was anxious for the proptosis to be reduced a course of X-ray therapy directed at the retro-orbital area was given. Although no measurements with the proptometer were made, there was objective and subjective improvement. A total of 2,000 r was given, over a period of ten days: 200 r for seven days, then 100 r, 250 r and 250 r on successive days.

SUMMARY

A case of Hand-Schüller-Christian syndrome of at least six years' duration in a man aged 47 is described. There was exophthalmos and wasting of the mandible, extensive and typical bone change but no diabetes insipidus and the blood cholesterol was normal.

My thanks are due to Professor de Wesselow, under whose care the patient was, for permission to publish the details of this case.

clinically evident and those that are silent, make it important to adopt any form of treatment which by raising the patient's resistance will have a general effect. The value of constitutional treatment in this respect is recognized. The effect of operation on raising resistance should also be considered.

I have formed an impression that benefit is gained in many cases by operation and that such benefit is not only local but general. Operation might raise resistance either by removing a source of tuberculous toxæmia, or by liberating into the tissues tuberculous inflammatory products which might act as specific antigens. Such a process might account for the beneficial effect of laparotomy in tuberculous peritonitis. Two observations may be quoted in favour of there being some benefit due to auto-inoculation. The first is the marked improvement in the general condition which may follow operation on tuberculous bone. This observation has been noted by others, notably Lavallo and McCrae Aitken. Certainly it has been confirmed in my experience. The effect may follow simple osteotomy through tuberculous bone without the removal of any tuberculous tissue. The second observation is the poor result which so frequently follows treatment of a tuberculous joint by amputation of the limb. Of 10 cases which had had an amputation only 3 remained permanently well. 3 died and 4 developed tuberculous lesions in other parts of the body.

I therefore examined the records of 129 patients admitted to Black Notley during the past ten years; these patients had skeletal tuberculosis complicated by associated tuberculous lesions, either in other parts of the skeleton, in the lungs, the genito-urinary system or the salpinges. These patients were divided into two groups, one of 49 cases who had had any operation into tuberculous tissue from which an auto-inoculation effect might have been obtained, and the other of 80 cases who had had no such operation. In assessing the results it appeared that some of the patients in the non-operated group might have been patients who were too advanced for operation and that this would spoil the two groups for the purpose of comparison. Therefore I subdivided the cases in both operated and non-operated groups into cases of moderate severity and marked severity, and the results into three groups, good, moderate and poor.

It was found that the percentage of cases of those who did well was quite high in both groups, 73.5% in the operated group and 66.3% in the non-operated group. This would be expected in any series of tuberculous patients treated thoroughly by constitutional measures and splintage. In the operated group 14.3% had moderate results, in the non-operated group 8.7%; there were poor results in 8.2% of the operated group and in 7.5% of the non-operated. Deaths in the operated group were 4%, in the non-operated 17.5%. Yet the percentage of cases of marked severity in the operated group was 28.5%, in the non-operated group 17.5%. So that the operated group was not a favoured group: yet the results were better in this group.

Though these figures may not be statistically significant they do tend to support the other evidence. It appears that especially in the desperate cases operation may carry benefit. There is no valid reason for withholding operation from patients with multiple tuberculous lesions, and their prognosis is better with operation than without. There is reason to believe that this may be due to an auto-inoculation effect.

No patient developed a permanent sinus following operation. Operation should not be done until a fair degree of resistance has been established, or miliary tuberculosis may supervene.

The Treatment of the Uncorrected Clubfoot in Childhood

By J. S. BATCHELOR, F.R.C.S.

I PROPOSE to describe a method of treatment that I have found useful for uncorrected, or imperfectly corrected, clubfeet in young school children: that is, in children from the age of 5 years to 10 or 12, when they are old enough to have a formal arthrodesis done if this should be necessary.

I have been much impressed by the disability that the uncorrected clubfoot produces in children in this age-group, for many of them are greatly handicapped in walking and have considerable difficulty with footwear. Moreover, they are frequently subjected to repeated manipulations, wrenchings and plaster immobilization of their deformed feet.

The results of this conservative treatment cannot be considered satisfactory. Manipulative trauma tends to produce a vicious circle of false correction, increasing fibrosis

The foot is held plantar-flexed and everted, and the position checked by X-ray. The posterior aspect of the talus is now exposed by vertical incision lateral to the tendo achillis (fig. 2).

The point of a Hey-Groves director is applied to the medial side of the head of the talus, and a guide wire introduced immediately above the ridge separating the ankle from the subtalar joint. The guide is introduced $4\frac{1}{2}$ cm. and a check X-ray taken.

The guide wire is now withdrawn and the track enlarged with drills until the graft can be hammered home. The graft lies above and parallel to the subtalar joint and in the long axis of the bone (fig. 3).

FIG. 2.

FIG. 3.

FIG. 4.

The wound is now closed and the foot can be safely dorsiflexed to a right angle. It is plastered in this position.

The anatomical and functional results in three cases have been excellent, and at five months there is no evidence of avascular necrosis of the body of the talus (fig. 4).

The Treatment of Bone Tuberculosis in Relation to Multiple Tuberculous Lesions

By M. C. WILKINSON, M.B.

MULTIPLICITY of tuberculous lesions undoubtedly makes the prognosis of tuberculosis worse: in this respect associated lesions in the skeleton are of only slight consequence, associated lesions in the genito-urinary tract are of more significance, and associated pulmonary tuberculous lesions may be the most grave. Nevertheless complete recovery can occur in spite of multiple lesions.

In discussing tuberculous lesions associated with bone tuberculosis I would distinguish between tuberculosis of the lymphatic glands, which I believe exercise a barrier effect against invasion of the blood-stream, and hæmatogenous tuberculous foci. The two types do not usually exist together. If there is a heavy glandular infection this is evidence of good resistance of the lymphatic tissues; if there are multiple hæmatogenous lesions, I think that the lymphatic tissues at the portal of entry have been inadequate. Similarly a good relative lymphocytosis is evidence of activity of the lymphatic defence and is of good prognostic import. As the lymphatic tissues reach their peak of activity during childhood, and wane gradually after adolescence, it is not surprising to find that the majority of childhood lesions are in the lymphatic glands, that skeletal lesions occur only in a minority of infected children, that multiple lesions tend to occur more frequently after adolescence, and that the incidence of multiple lesions increases as age advances. As a corollary it follows that when a patient has both a skeletal lesion and associated gross tuberculous lymphadenitis the prognosis for the skeletal lesion is usually very good, as the patient's resistance is high. With regard to associated lesions other than in the lymphatic system, the incidence in a series of 340 cases of skeletal tuberculosis was 25.3%. Nevertheless this must be a gross understatement of the incidence of such lesions as with improved methods of diagnosis it is easier to detect silent lesions, often present, and previously only suspected. The wide distribution in the body of hæmatogenous tuberculous lesions, both those that are

clinically evident and those that are silent, make it important to adopt any form of treatment which by raising the patient's resistance will have a general effect. The value of constitutional treatment in this respect is recognized. The effect of operation on raising resistance should also be considered.

I have formed an impression that benefit is gained in many cases by operation and that such benefit is not only local but general. Operation might raise resistance either by removing a source of tuberculous toxæmia, or by liberating into the tissues tuberculous inflammatory products which might act as specific antigens. Such a process might account for the beneficial effect of laparotomy in tuberculous peritonitis. Two observations may be quoted in favour of there being some benefit due to auto-inoculation. The first is the marked improvement in the general condition which may follow operation on tuberculous bone. This observation has been noted by others, notably Lavallo and McCrae Aitken. Certainly it has been confirmed in my experience. The effect may follow simple osteotomy through tuberculous bone without the removal of any tuberculous tissue. The second observation is the poor result which so frequently follows treatment of a tuberculous joint by amputation of the limb. Of 10 cases which had had an amputation only 3 remained permanently well. 3 died and 4 developed tuberculous lesions in other parts of the body.

I therefore examined the records of 129 patients admitted to Black Notley during the past ten years; these patients had skeletal tuberculosis complicated by associated tuberculous lesions, either in other parts of the skeleton, in the lungs, the genito-urinary system or the salpinges. These patients were divided into two groups, one of 49 cases who had had any operation into tuberculous tissue from which an auto-inoculation effect might have been obtained, and the other of 80 cases who had had no such operation. In assessing the results it appeared that some of the patients in the non-operated group might have been patients who were too advanced for operation and that this would spoil the two groups for the purpose of comparison. Therefore I subdivided the cases in both operated and non-operated groups into cases of moderate severity and marked severity, and the results into three groups, good, moderate and poor.

It was found that the percentage of cases of those who did well was quite high in both groups, 73.5% in the operated group and 66.3% in the non-operated group. This would be expected in any series of tuberculous patients treated thoroughly by constitutional measures and splintage. In the operated group 14.3% had moderate results, in the non-operated group 8.7%; there were poor results in 8.2% of the operated group and in 7.5% of the non-operated. Deaths in the operated group were 4%, in the non-operated 17.5%. Yet the percentage of cases of marked severity in the operated group was 28.5%, in the non-operated group 17.5%. So that the operated group was not a favoured group: yet the results were better in this group.

Though these figures may not be statistically significant they do tend to support the other evidence. It appears that especially in the desperate cases operation may carry benefit. There is no valid reason for withholding operation from patients with multiple tuberculous lesions, and their prognosis is better with operation than without. There is reason to believe that this may be due to an auto-inoculation effect.

No patient developed a permanent sinus following operation. Operation should not be done until a fair degree of resistance has been established, or military tuberculosis may supervene.

The Treatment of the Uncorrected Clubfoot in Childhood

By J. S. BATCHELOR, F.R.C.S.

I PROPOSE to describe a method of treatment that I have found useful for uncorrected, or imperfectly corrected, clubfeet in young school children; that is, in children from the age of 5 years to 10 or 12, when they are old enough to have a formal arthrodesis done if this should be necessary.

I have been much impressed by the disability that the uncorrected clubfoot produces in children in this age-group, for many of them are greatly handicapped in walking and have considerable difficulty with footwear. Moreover, they are frequently subjected to repeated manipulations, wrenchings and plaster immobilization of their deformed feet.

The results of this conservative treatment cannot be considered satisfactory. Manipulative trauma tends to produce a vicious circle of false correction, increasing fibrosis

and stiffness, followed by inevitable relapse of deformity and yet more manipulations and wrenchings.

In congenital clubfoot the deformity occurs essentially at the astragalo-calcaneo-scapoid joint. The os calcis moves with the forefoot and if the deformity at the astragalo-scapoid joint can be corrected by drawing the scaphoid around the head of the astragalus the inversion of the heel will disappear.

In the uncorrected clubfoot the scaphoid is tucked around on the inner side of the head of the astragalus and is tethered in this position by contracture of soft tissues, particularly by the inferior and internal calcaneo-scapoid ligaments. The net result of this is that the astragalus is relatively too long and it is impossible to draw the scaphoid around it.

FIG. 1.

and inferior calcaneo-scapoid ligaments can be exposed and divided, thus freeing the head of the astragalus and enlarging its socket. This should allow the scaphoid to be drawn up and out around the head of the astragalus, and it will now be found that

I overcome this difficulty by shortening the astragalus by excising a section of bone from its neck (fig. 1). The operation is performed through a two-inch longitudinal incision over the neck of the astragalus, which lies, in the uncorrected clubfoot, on the outer side of the dorsum of the foot. The neck is exposed subperiosteally and bone levers, the points of which engage the sinus tarsi, are placed on either side. A section of bone, approximately one-third of an inch wide, is now removed, the proximal osteotomy being made as far back as possible in order to avoid encroaching too closely on the articular surface of the head. When the capsule on the dorsum and inner side of the astragalo-scapoid joint has been incised the internal

The foot after operation.

the gap in the neck is closed. The foot is fixed in plaster in the maximum degree of valgus, further correction of the deformity being frequently obtained at the routine change of plaster in a fortnight's time. Immobilization is maintained for four to five months and the child is then provided with an inside iron, outside T-strap and quarter-inch outside wedge on the sole of the boot.

Nine cases, in four of which the deformity was bilateral, making thirteen feet, have been treated. The operation should not be performed on children below the age of 5, the average age at operation in this series being 6. Satisfactory functional results were obtained in ten feet; in the remaining three the deformity recurred soon after operation.

It is not claimed that this treatment gives the patient anything approaching a perfect foot. It is, however, a simple method which attacks the main site of the deformity and produces a mobile, plantigrade foot on which the child can get about reasonably well until it is old enough to have a formal arthrodesis if this should be necessary. Movement at the astragalo-scapoid and sub-astragaloid joints is preserved and providing the operation is done at the right age growth is not seriously disturbed (fig. 2, a, b and c).

Sacro-iliac Arthrodesis

By P. H. NEWMAN, D.S.O., F.R.C.S.

This paper gives the results of a follow-up examination of a series of sacro-iliac arthrodesis operations performed for sacro-iliac strain by Mr. A. S. Blundell Bankart.

In every case the condition had been previously treated by one or more manipulations and had failed to respond. 36 operations were performed on 32 patients during the last ten years and during the same period approximately 500 manipulations were performed for this condition. Roughly speaking it can be said that 1 in 15 patients manipulated were eventually arthrodesed.

The Smith Petersen type of operation was used in each case and followed by a four-week rest period in bed.

RESULTS

The results were divided into cures, partial cures and failures. Cures were those who were quite definite about the relief given to them by the operation and who had suffered nothing more than a minor ache or pain in the back since. Partial cures were those who had been relieved of the original pain but complained of scar tenderness, lumbosacral aching or other non-incapacitating attacks of moderate or minor pain in this area. Failures were those not fitting into either of these two categories.

TABLE I.—SACRO-ILIAC ARTHRODESIS.
36 Operations Performed on 32 Patients.

21 were cures
6 were partial cures
6 were failures
3 were untraced
29 were females, 3 were males
Average follow-up time just over four years.

TABLE II.—SACRO-ILIAC ARTHRODESIS.
The history of an accident and the average age differed in the three groups as follows:—

History of accident	Average age
Cures 47%	31.4 years
Part. cures 0%	33.2 years
Failures 0%	42.4 years

In the tidal wave of ruptured intervertebral disc which has swept over and swamped the field of back and radiating leg pain the sacro-iliac syndrome is one of the islands which as yet remains unsubmerged. It is important therefore to have a clear concept of what is meant by sacro-iliac strain and what are the symptoms associated with it. Superficially the two syndromes may resemble each other. A history of injury followed by recurrent acute or chronic back and radiating lower limb pain. Lumbosacral pain may occur secondary to sacro-iliac conditions giving tenderness and stiffness in this area. On deeper inquiry the two syndromes differ considerably. The nature of the accident is often a torsion strain either in the standing or sitting position. It is uncommon in the male occurring almost invariably in females between the ages of 15 and 45.

and stiffness, followed by inevitable relapse of deformity and yet more manipulations and wrenchings.

In congenital clubfoot the deformity occurs essentially at the astragalo-calcaneo-scapoid joint. The os calcis moves with the forefoot and if the deformity at the astragalo-scapoid joint can be corrected by drawing the scaphoid around the head of the astragalus the inversion of the heel will disappear.

In the uncorrected clubfoot the scaphoid is tucked around on the inner side of the head of the astragalus and is tethered in this position by contracture of soft tissues, particularly by the inferior and internal calcaneo-scapoid ligaments. The net result of this is that the astragalus is relatively too long and it is impossible to draw the scaphoid around it.

FIG. 1.

and inferior calcaneo-scapoid ligaments can be exposed and divided, thus freeing the head of the astragalus and enlarging its socket. This should allow the scaphoid to be drawn up and out around the head of the astragalus, and it will now be found that

I overcome this difficulty by shortening the astragalus by excising a section of bone from its neck (fig. 1). The operation is performed through a two-inch longitudinal incision over the neck of the astragalus, which lies, in the uncorrected clubfoot, on the outer side of the dorsum of the foot. The neck is exposed subperiosteally and bone levers, the points of which engage the sinus tarsi, are placed on either side. A section of bone, approximately one-third of an inch wide, is now removed, the proximal osteotomy being made as far back as possible in order to avoid encroaching too closely on the articular surface of the head. FIG. 2c. October 1945.

Assuming this to be the site of the true axis of rotation it is simple to imagine the relative movements of the lumbar spine and sacrum (fig. 1).

FIG. 1.—Rotation of sacro-iliac joint on transverse axis.

As the lordosis increases the greater becomes the backward tilting of the sacrum and the greater the diameter of the inferior pelvic outlet (fig. 2).

FIG. 2.—Movements of sacro-iliac joints (after Brooke, 1924).

The range of movement in relation to sex and age has been carefully plotted by Brooke (fig. 2). A small equal range is present in both sexes up to the age of puberty. In the male from then onwards there is a slowly-decreasing range until by the sixth or seventh decade it is negligible. In the female the range increases sharply up till the age of 25 and then slowly declines but even late in life there is quite an appreciable range of movement. In pregnancy the range increases tremendously to reach at term a degree twice as much as that at 25. It has been found that at full term the anterior margins of the joint can be separated by $\frac{1}{4}$ in. It is during the child-bearing age that sacro-iliac strain typically occurs. It is during the same period that there is the greatest range of movement. It is not unreasonable therefore to associate strain with the increase of the range of movement. The female needs the additional range of movement but has thereby to sacrifice stability.

The articular surfaces are irregular and present numerous crests, depressions and tubercles. When these are held tightly interlocking, as in the male, it is unlikely that

There may be a history of clicking, especially on sitting down, which is localized accurately to the sacro-iliac joint. The patient may be able to say when the joint goes in and when it goes out.

The main point in the diagnosis, however, is the site of pain and tenderness. This is invariably found just medial to the posterior superior spine or at the upper margin of the great sciatic notch. Without this it is difficult to see how the diagnosis can be made. The importance of this sign can be seen when it is realized that every patient in Smith Petersen's series of 26 cases and every patient in this series and all but one in Haldeman and Hall's series of 42 exhibited pain and tenderness over the joint.

Radiating pain.—Associated pain was found in the following areas: (1) The lumbosacral area. (2) Groin and lateral thigh. (3) Posterior thigh and leg. (4) Lateral buttock.

The lumbosacral pain can be easily explained. With a painful and guarded sacro-iliac joint the lumbosacral joint is called upon to carry out a degree of movement to which it is unaccustomed.

A pain radiating round to the groin or down the lateral side of the thigh was frequently present. Typically it was described by placing the hand round the top of the thigh pointing obliquely downwards, towards the perineum. There was no doubt about this pain for patients describing the pre-operative symptoms some long time after operation described it without being prompted by leading questions. It is peculiar that neither Smith Petersen, in his most comprehensive article on the symptomatology of this condition, nor Haldeman and Hall mention it.

It was present in 13 of the 32 patients of this series.

This pain is in the lumbar 1 and 2 distribution and the explanation of it has so far evaded me. Neither from the literature nor from various authorities has a solution been forthcoming. It cannot be described as a referred pain associated with the nerve supply of the joint as this is derived from L. 5, S. 1 and 2.

It cannot be described as a periarticular involvement of the nerves supplying this area as these have no intimate relation to the joint in question. Whatever be the origin of this pain we consider it to be a symptom typical of and valuable in the diagnosis of sacro-iliac strain.

The pain which radiates down the back of the thigh, leg and even into the foot offers three possible explanations.

- (1) A referred pain associated with the nerve supply of the joint.
- (2) A periarticular involvement of the lumbosacral, sacral 1 or sacral 2 nerve roots which have a very close relation to the joint.
- (3) An involvement of the roots by some pathological process higher up, in the nature of intervertebral arthritis or a ruptured intervertebral disc.

Sacro-iliac strain.—If an abnormal or excessively strong force is put upon a joint it is liable to produce a strain of the ligaments of that joint. This may result from an external force or by faulty mechanism due to an internal derangement. The latter case is aptly demonstrated by the loose body in the knee which insinuates itself between the moving articular surfaces thus altering the axis of rotation and throwing a tremendous strain upon the ligaments.

In the strained joint we may picture the ligaments as partially torn and pulled from their attachments. Fortunately the body has a power of recuperation and the lesion may recover completely. Should the recovery be hindered by repeated trauma, faulty posture or too long immobilization then a condition of chronic strain may result.

The movement in the sacro-iliac joint is of two types. A rotational movement and a transverse movement. The former would appear to be the more important and occurs round a transverse horizontal axis which passes through the anterior margin of the joint at the junction of the two arms of the auricular shaped articular surface at the level of the second sacral vertebra.

Brooke after examining 200 post-mortem specimens described a tubercle situated on the sacral surface which fitted into a cavity on the opposing surface at the level of the second sacral vertebra. Quain's anatomy also describes this tubercle.

Assuming this to be the site of the true axis of rotation it is simple to imagine the relative movements of the lumbar spine and sacrum (fig. 1).

FIG. 1.—Rotation of sacro-iliac joint on transverse axis.

As the lordosis increases the greater becomes the backward tilting of the sacrum and the greater the diameter of the inferior pelvic outlet (fig. 2).

FIG. 2.—Movements of sacro-iliac joints (after Brooke, 1924).

The range of movement in relation to sex and age has been carefully plotted by Brooke (fig. 2). A small equal range is present in both sexes up to the age of puberty. In the male from then onwards there is a slowly-decreasing range until by the sixth or seventh decade it is negligible. In the female the range increases sharply up till the age of 25 and then slowly declines but even late in life there is quite an appreciable range of movement. In pregnancy the range increases tremendously to reach at term a degree twice as much as that at 25. It has been found that at full term the anterior margins of the joint can be separated by $\frac{1}{4}$ in. It is during the child-bearing age that sacro-iliac strain typically occurs. It is during the same period that there is the greatest range of movement. It is not unreasonable therefore to associate strain with the increase of the range of movement. The female needs the additional range of movement but has thereby to sacrifice stability.

The articular surfaces are irregular and present numerous crests, depressions and tubercles. When these are held tightly interlocking, as in the male, it is unlikely that

the surfaces will move on each other even in the severest strain. As the ligaments slacken up movement occurs and when a crest surmounts a crest then will great strain be thrown upon the ligaments of the joint.

Not only is there an increase in the vertical stretch but also sideways. When the ligaments loosen up still more crest may surmount crest with impunity and this may be imagined to be the position in a woman who feels her joint slip in and out without pain.

In conclusion I wish to stress the importance of separating the sacro-iliac from the lumbar spine syndrome.

Favourable points, indicating operation.—Age between 16 and 40. History of accident or sudden onset. Definite localized pain and tenderness. Anterior and lateral thigh pain. Clicking when sitting down. Manipulation should have failed before recommending operation.

Unfavourable points.—Age over 40. Spinal arthritis. Psychoneurotic type. A long history of poorly localized or generalized pain. A demoralizing gynecological or obstetrical history.

In carefully selected cases sacro-iliac arthrodesis is a good operation.

Arterial Advances of Orthopædic Concern

By SOL. M. COHEN, M.A., F.R.C.S.

CLINICAL CONSIDERATIONS

FROM Lewis' vast contributions on the principles of the circulation I will mention only a few fundamental points:—

(a) The skin and muscle circulations are each under triple control—local chemical, hormonal and nervous. Changes may occur in the skin with opposite or no changes in the muscle, and a warm-skinned limb may have poor or even dead muscles beneath. A relatively small blood-flow is sometimes sufficient to maintain a normal skin temperature. The local metabolites of muscle exercise, in the main, regulate the muscle circulation. The orthopædic surgeon has in recent years applied this knowledge, particularly in reabling. Quite ten years ago Fagge, of Guy's, said that: "Physiological rest does not imply immobility . . . it is the acquisition of a state of *eased function* favourable to repair."

(b) After arterial arrest in the ischæmic limb loss of sensation followed by motor power does not ensue until fifteen to thirty minutes later, due to interference with nerve conduction; and loss of power is often a valuable signal as to whether the plaster or the splint is too tight.

(c) The ischæmic limb may feel to the patient nerveless and dead; there will be pain, only if the limb has been exercised to arterial arrest.

(d) Tissues with specialized function vary in the time that they can withstand arterial arrest. Muscle will survive six to ten hours, nerve twelve to twenty-four hours, skin twenty-four to forty-eight hours.

(e) The dangers of overheating ischæmic tissues are appreciated to-day, but the pendulum has swung extravagantly to extreme cold. Icing is dangerous; tissues are damaged directly, metabolite formation interfered with, and oxyhæmoglobin will not dissociate below 10° C. Icing, I believe, should be reserved for the dead limb; amputation under ice anaesthesia is a first-class new method in selected cases. So much for the clinical facts.

General condition and limb survival.—We now realize the importance of the general condition for the survival of the limb. Rapid massive blood transfusions are an enormous advance. Powerful peripheral vasoconstriction otherwise clinically is maintained

in the large vessels and the arterioles. Shakespeare seemed to know something of this when he made Hamlet say:

"My fate cries out,
And makes each petty artery in this body
As hardy as the Nemean lion's nerve."

Experiment seems to indicate that one of the most important factors in collateral vessel dilatation is a good pressure head within the vessel lumen. With a sluggish circulation the arterial inflow must, to a great extent, be dependent on the venous outflow. It does not seem good advice, therefore, to nurse the limb, as was advocated both in the B.L.A. and Middle East campaigns, in the dependent position. Such venous stagnation, in an area filled with all the factors favouring thrombosis, is likely to prejudice the already sluggish arterial inflow. We must not forget, too, the value of the lymphatic system as an accessory circulation—a scavenger; elevation of the limb (heart-level) will assist the flow and compensate to some extent the ischæmic loss of muscle power. Orthopædists are aware of the stiff clawed toes in many of these cases, due to the periarticular coagulation of the stagnating lymph; such joints need to be passively moved in the ischæmic limb, just as do the joints after nerve section.

The role of the sympathetic system.—Modern opinion views the sympathetic system more and more as an effector mechanism, with no sensory fibres. Sympathetic block or section increases the skin circulation, is of value for the skin or the hand-foot lesion, but has little effect on the muscle lesion. Boyd [1] has recently urged that no major vessel should be tied without at the same time sympathetic interruption. I do not agree. To dilate the skin vessels—which of course we can achieve as easily, reflexly, by merely heating the patient—may be hazardous. It leads to pooling of blood and its soaking up in a spongy unessential area, thus depriving the deeper vessels. With any vessel ligature, arteriography shows that the blood seeks to find its way into the main deeper channels; unless that flow is maintained, fairly briskly, thrombosis ensues. I need only quote the latest paper of 100 major vessel injuries in war by Rose, Hess and Welch [2]. Their limb mortality, despite routine sympathetic blocks, is high, and I quote their blunt comment "in no case did this procedure appear to reverse the progress from an avascular state in patients with severed arteries."

DeBakey and Simeone [3] have analysed 2,471 arterial injuries in American battle casualties; 30 out of 42, who had sympathectomies, lost their limbs (the severer cases may, of course, have been selected for this procedure). The real test of the value of sympathetic block is as to whether it could save the limb with popliteal vessel injury. I can quote a large number of cases where this procedure made no difference; associated damage to the collaterals had long sealed the fate of the limb. Sympathectomy preliminary to operation for the arterial or arteriovenous aneurysm was much mooted in the early years of the war; it seems unnecessary. Elkin [4], who has probably had the most extensive experience any surgeon is ever likely to have, has published astonishing figures. He has treated some 106 false aneurysms in which some form of major vessel interruption became necessary. In no case did he perform sympathectomy, none developed gangrene or other untoward ill-effects in the distal limb. Neither Learmonth [5] nor Maybury [6] now do pre-operative sympathectomies. I would touch also on one further fact about sympathectomy. Pre-ganglionic section is now the fashion. Everyone who has done any sympathectomies will have observed, and anatomists (Pick and Sheehan [7]) have recently confirmed, the extraordinary variations in the anatomy of the ganglia and the rami. We run considerable risk of doing an incomplete operation, and ganglionectomy may well come into favour again. The results after pre-ganglionic section have not been startlingly better; even with this procedure there is an increased sensitivity to adrenaline-like substances. Grimson [8], in a recent very able review, backs with emphasis the radical ganglionectomy procedure. Certainly for the leg I invariably remove, as well, the fourth lumbar ganglion. Lastly, it is perhaps right that we maintain an attitude of scepticism to the idea that sympathetic fibres have remarkable navigational qualities through fibrous tissue, and can seek and find out the opposite cut end. Its powers of regeneration are no greater than that of any peripheral nerve. This "apparent" regeneration is capable of simple explanation. Any operation on the sympathetic system, involving as it does much stripping and bruising of the sympathetic trunk, must necessarily contuse or render ischæmic the ganglia and fibres. Nerve conduction is interfered with, and the "incomplete" operation gives at first a good result: later, the nerve fibres within intact sheaths recover and spoil the end-result.

the surfaces will move on each other even in the severest strain. As the ligaments slacken up movement occurs and when a crest surmounts a crest then will great strain be thrown upon the ligaments of the joint.

Not only is there an increase in the vertical stretch but also sideways. When the ligaments loosen up still more crest may surmount crest with impunity and this may be imagined to be the position in a woman who feels her joint slip in and out without pain.

In conclusion I wish to stress the importance of separating the sacro-iliac from the lumbar spine syndrome.

Favourable points, indicating operation.—Age between 16 and 40. History of accident or sudden onset. Definite localized pain and tenderness. Anterior and lateral thigh pain. Clicking when sitting down. Manipulation should have failed before recommending operation.

Unfavourable points.—Age over 40. Spinal arthritis. Psychoneurotic type. A long history of poorly localized or generalized pain. A demoralizing gynaecological or obstetrical history.

In carefully selected cases sacro-iliac arthrodesis is a good operation.

Arterial Advances of Orthopædic Concern

By SOL. M. COHEN, M.A., F.R.C.S.

CLINICAL CONSIDERATIONS

FROM Lewis' vast contributions on the principles of the circulation I will mention only a few fundamental points:—

(a) The skin and muscle circulations are each under triple control—local chemical, hormonal and nervous. Changes may occur in the skin with opposite or no changes in the muscle, and a warm-skinned limb may have poor or even dead muscles beneath. A relatively small blood-flow is sometimes sufficient to maintain a normal skin temperature. The local metabolites of muscle exercise, in the main, regulate the muscle circulation. The orthopædic surgeon has in recent years applied this knowledge, particularly in reabbling. Quite ten years ago Fagge, of Guy's, said that: "Physiological rest does not imply immobility . . . it is the acquisition of a state of *eased function* favourable to repair."

(b) After arterial arrest in the ischaemic limb loss of sensation followed by motor power does not ensue until fifteen to thirty minutes later, due to interference with nerve conduction; and loss of power is often a valuable signal as to whether the plaster or the splint is too tight.

(c) The ischaemic limb may feel to the patient nerveless and dead; there will be pain, only if the limb has been exercised to arterial arrest.

(d) Tissues with specialized function vary in the time that they can withstand arterial arrest. Muscle will survive six to ten hours, nerve twelve to twenty-four hours, skin twenty-four to forty-eight hours.

(e) The dangers of overheating ischaemic tissues are appreciated to-day, but the pendulum has swung extravagantly to extreme cold. Icing is dangerous; tissues are damaged directly, metabolite formation interfered with, and oxyhaemoglobin will not dissociate below 10° C. Icing, I believe, should be reserved for the dead limb; amputation under ice anaesthesia is a first-class new method in selected cases. So much for the clinical facts.

General condition and limb survival.—We now realize the importance of the general condition for the survival of the limb. Rapid massive blood transfusions are an enormous advance. Powerful peripheral vasoconstriction otherwise clinically is maintained

Advances in surgery of access.—This has been developed particularly for dealing with the arterial aneurysm or the arteriovenous fistula.

(a) Proximal control is now invariably sought before exposing the aneurysm sac. For the common femoral aneurysm I would endorse the advice of Holman [14], that both the common iliac and external iliac need temporary ligatures. I would commend this to the orthopaedic surgeon for use prior to hip disarticulation, and it may well be of assistance for reconstructive operations on the hip-joint. The vessels are easily exposed by a transverse gridiron incision and extraperitoneal stripping. A word of warning. Tape over a segment of rubber tubing is these days preferred to the Crile clamp. The tape knot, however, slides in jerky fashion, and I have myself tied it too tightly and damaged the vessel. I now paraffin the tape, and Crile's clamps do not damage the vessels.

(b) Division of the clavicle or excision of a middle segment is a measure giving a first-class exposure for the axillary or subclavian aneurysm. Segment excision seems preferable, and I have been astonished at the painless free movements without loss of power after operation. This operation has been well described by Elkin [4a] recently.

(c) Excision of the upper end of the fibula too is a very useful measure for exposure of the aneurysm of the anterior tibial artery near its origin (Elkin [4b]).

(d) The aneurysm sac is now usually left in situ: the original operation of Matas, of opening the sac, seeing the vessel mouths and suturing them, does the least damage to the collaterals.

(e) The exact cardiac output and the load of the heart in the arteriovenous aneurysm can now be determined by the method of cardiac catheterization (McMichael and Sharpey Schafer [15]; Cohen [9a]). It provides accurate information as to whether the fistula in hazardous position should be operated on.

In vascular operations for the thigh the ordinary blood-pressure tourniquet band is too short, and two blood-pressure bags—front and back—are useful. Where there is much bleeding, and one is anxious to get the vessel point, I advise the use of two suckers; diathermy is invaluable; drainage is a courier of sepsis; prophylactic penicillin after the vascular operation is to be recommended. To the surgeon's armamentarium has also been added in this war fibrin foam as a hemostatic agent; we now have an absorbable pack—oxidized cellulose—and recently gelatine sponge [16] has given us for the thrombin a matrix which is universal, free from danger of antigenicity, with little local tissue reaction, and readily procurable. When it comes to amputating the ischaemic limb, experience gathered in the B.L.A. campaign seems to be of value; by dissecting skin flaps, coring out the dead muscle, a skin-bone stump can often be left, which although short is still very useful.

Muscle biopsy has been actively undertaken in World War II, and has taught us not only about recovering nerve lesions, but also about the distinctive appearance of dying ischaemic muscle. Whether temporary arterial or venous obstruction be responsible for the Volkmann's lesion they both may give the same ultimate result, although there is some difference in the primary microscopical picture [17]. These cases should not be stretched too early. No amount of splinting will check the impending Volkmann's contracture in the leg, and much harm may be done to the anaesthetic sole by excessive splintage. Untoward effects in the limb may follow the ischaemia, even if no gangrene or Volkmann's contracture result, and Athol Parkes [18] has drawn attention to the anaesthesia, the delayed pain responses and intrinsic muscle atrophy that may follow the too tight plaster or the very oedematous limb. I have seen the same effect even when there has been no plaster or excess oedema, and these nerve effects may be directly consequent on the ischaemia itself.

Vascular reflexes.—Before the last war there was much ado about local reflexes arising from the bruised vessel and reflex spasm of the collaterals; arterectomy to break such reflex arcs was usual. It seems a bad operation; if there is any collateral vessel damage the surgeon has added the *coup de grâce* to the limb (Cohen [9]).

Lewis declared that there was no physiological sanction for this theory of reflex spasm of the collaterals from the bruised vessel. An advance in the treatment of the arterial bruise is the advice of Maybury [6] to oversew it with muscle or local tissue, to assist the localization of the hæmatoma and the formation of an aneurysm, in the event of rupture. Such a bruised vessel does not necessarily predispose to secondary distal clot formation, and I have seen several cases where only a local blockage was subsequently maintained.

Arterial spasm.—There are two types of arterial spasm: (a) benign or segmentary spasm; there is a direct vessel blow with twanging by bone fragment or "near miss". If found at operation—as for the supracondylar fracture—experience seems to indicate that it is best left alone. Such exploration is of value, for time and again the vessel is found trapped between the bone ends or sharply angulated (the latter stretching will obliterate also the collateral vessel mouths—much as stretching rubber tubing narrows it—and explains why in some cases arterectomy appears to have been of value). (b) The second type of spasm is reflex; the local tissues have here received a severe local blow, but the cushioned vessel has had no direct damage. Such arterial spasm is often malignant in its obstinacy.

Arteriography.—Diodone—an organic iodine compound—is a safe medium—I use "Pyclosil" 35%. Arteriography is of use for:

- (a) Studying the collateral vessel path.
- (b) Locating the site of an embolus and placing the site of a fistula in an arterio-venous aneurysm.
- (c) In arteriosclerotics in deciding as to whether a below-knee amputation will be safe. Time and again in the arteriosclerotic, one finds a local block in the region of Hunter's canal. In some of these cases it would appear that vein grafting may become a practical possibility. (Dickson Wright has already done this.—Personal communication.)

Heparin.—Unfortunately this has been in short supply during the war. Interrupted injections are unreliable, and the continuous drip is to be preferred. The recent introduction of Pitkin's menstruum as a conveyer for heparin [10] allows it to be deposited subcutaneously and to maintain a uniform therapy. As, time and again, thrombosis in the artery or veins seals the fate of the limb, heparin may well come to play an important rôle, not only after suture, but also for the limb with sluggish circulation. As orthopaedic surgeons come to evaluate their results in their older patients they will find that pulmonary embolus takes quite a toll. In the intratrochanteric type of fracture the Americans already point to its high incidence, and list it as the most frequent cause of death (Golodner, Morse and Angrist [11]). Heparin may be used but thrombosis often comes on, even so, some time after its discontinuation. Interruption of the femoral vein is a new safety measure that I have myself used, and feel that it has great possibilities.

Vein grafting.—The vitallium cannula method of vein grafting has been hailed by Matas—the Nestor of Vascular surgery—as "the greatest advance in peripheral vascular surgery in the last twenty-five years". Blakemore and Lord's [12] results experimentally, and in the cases published, are amazing and its use by Whipple in portal hypertension has opened up a complete new approach to the subject. From the experience of American and Canadian friends one can say that: (a) The technique is not easy, and unless carried out carefully may lead to destroying or blockage of important collaterals. (b) Where the ligature holds the cannula the vessel sloughs and the graft lies somewhat perilously after the fourth day. Rose, Hess and Welch [2] have reported on its use in 8 war injuries; 1 died on the table, and 5 out of the other 7 developed gangrene. They consider that thrombosis and spasm caused the death of these limbs. DeBakey and Simeone [3] have collected information on 40 cases—the limb mortality was 57.5%. However, there is no doubt that vessel ligature in war carried an extraordinarily high limb mortality; 50 to 70% for the femoral, and higher for the popliteal. Arterial sutures should receive more trial in civil surgery. When this is not possible, the experience of Mustard [13] (3 cases), American surgeons (14 cases)—and I have had one case—of using glass, or possibly plastic cannulae, may revive a useful method for tiding the limb over. The dislocated knee with popliteal artery injury, in my experience, usually has extensive damage to the collaterals; if such limbs are to be saved, then some form of vessel bridge seems essential.

Advances in surgery of access.—This has been developed particularly for dealing with the arterial aneurysm or the arteriovenous fistula.

(a) Proximal control is now invariably sought before exposing the aneurysm sac. For the common femoral aneurysm I would endorse the advice of Holman [14], that both the common iliac and external iliac need temporary ligatures. I would commend this to the orthopædic surgeon for use prior to hip disarticulation, and it may well be of assistance for reconstructive operations on the hip-joint. The vessels are easily exposed by a transverse gridiron incision and extraperitoneal stripping. A word of warning. Tape over a segment of rubber tubing is these days preferred to the Crile clamp. The tape knot, however, slides in jerky fashion, and I have myself tied it too tightly and damaged the vessel. I now paraffin the tape, and Crile's clamps do not damage the vessels.

(b) Division of the clavicle or excision of a middle segment is a measure giving a first-class exposure for the axillary or subclavian aneurysm. Segment excision seems preferable, and I have been astonished at the painless free movements without loss of power after operation. This operation has been well described by Elkin [4a] recently.

(c) Excision of the upper end of the fibula too is a very useful measure for exposure of the aneurysm of the anterior tibial artery near its origin (Elkin [4b]).

(d) The aneurysm sac is now usually left in situ: the original operation of Matas, of opening the sac, seeing the vessel mouths and suturing them, does the least damage to the collaterals.

(e) The exact cardiac output and the load of the heart in the arteriovenous aneurysm can now be determined by the method of cardiac catheterization (McMichael and Sharpey Schafer [15]; Cohen [9a]). It provides accurate information as to whether the fistula in hazardous position should be operated on.

In vascular operations for the thigh the ordinary blood-pressure tourniquet band is too short, and two blood-pressure bags—front and back—are useful. Where there is much bleeding, and one is anxious to get the vessel point, I advise the use of two suckers; diathermy is invaluable; drainage is a courier of sepsis; prophylactic penicillin after the vascular operation is to be recommended. To the surgeon's armamentarium has also been added in this war fibrin foam as a hæmostatic agent; we now have an absorbable pack—oxidized cellulose—and recently gelatine sponge [16] has given us for the thrombin a matrix which is universal, free from danger of antigenicity, with little local tissue reaction, and readily procurable. When it comes to amputating the ischæmic limb, experience gathered in the B.L.A. campaign seems to be of value; by dissecting skin flaps, coring out the dead muscle, a skin-bone stump can often be left, which although short is still very useful.

Muscle biopsy has been actively undertaken in World War II, and has taught us not only about recovering nerve lesions, but also about the distinctive appearance of dying ischæmic muscle. Whether temporary arterial or venous obstruction be responsible for the Volkmann's lesion they both may give the same ultimate result, although there is some difference in the primary microscopical picture [17]. These cases should not be stretched too early. No amount of splinting will check the impending Volkmann's contracture in the leg, and much harm may be done to the anæsthetic sole by excessive splintage. Untoward effects in the limb may follow the ischæmia, even if no gangrene or Volkmann's contracture result, and Athol Parkes [18] has drawn attention to the anæsthesia, the delayed pain responses and intrinsic muscle atrophy that may follow the too tight plaster or the very œdematous limb. I have seen the same effect even when there has been no plaster or excess œdema, and these nerve effects may be directly consequent on the ischæmia itself.

JOINT DISCUSSION No. 4

Section of Neurology with Section of Orthopædics

Chairman—J. PURDON MARTIN, M.D., F.R.C.P.

(President of the Section of Neurology)

[March 7, 1946]

DISCUSSION ON SPINAL CARIES WITH PARAPLEGIA

Professor H. J. Seddon, Nuffield Department of Orthopædic Surgery, Oxford: *The pathology of Pott's paraplegia.*

Between 1870 and 1900 the pathology of Pott's paraplegia attracted great attention: cellular pathology was making rapid strides, the disease was common and opportunities for post-mortem examinations not infrequent. The questions at issue were whether the lesion was a true myelitis, or the result of a pachymeningitis, or due to compressive changes affecting the arteries, veins or lymphatics of the spinal cord.

During the present century interest has flagged; however, the nature of cord compression in general has been worked out thoroughly, notably by Purves-Stewart and Riddoch (1923); in 1923 a valuable monograph on Pott's paraplegia was published by Sorrel-Déjerine, who put forward a new clinical-pathological classification; and in 1935 Butler and I published papers, covering most aspects of the disease, which were based on a review of 186 cases. Since that time I have seen some 40 more cases but what has been learned from them has concerned treatment rather than pathology, and the same seems to be true of other recent observers.

The thing that has emerged most clearly is the fairly sharp distinction between paraplegia occurring during the active phase of the spinal disease and that appearing at a much later date when, to all appearances, the vertebral lesion is well healed.

PARAPLEGIA OF EARLY ONSET

The intraspinal abscess.—Everyone is familiar with paraplegia occurring during the active phase of the spinal disease; indeed, derangement of locomotion is sometimes the presenting symptom. And it will not be disputed that in most cases the cause of the paraplegia is a tuberculous abscess, provided that the term abscess is used in a fairly wide sense so as to include any tuberculous inflammatory mass whether its contents are fluid or semi-solid. The abscess is usually in the thoracic region, where three factors favour involvement of the spinal cord: (1) The narrowness of the spinal canal; (2) the anterior concavity of the vertebral column which encourages angulation at the site of disease (fig. 1) and the squeezing of inflammatory products towards the cord (here it may be mentioned that there is clinical evidence (Goldthwait, 1889) to show that this factor is significant); and (3) the close confinement of the abscess by the stout anterior common ligament; where an abscess can escape—into the psoas muscle, for example—paraplegia does not occur and I have yet to see an exception to the rule that paraplegia due to compression by an abscess cannot coexist with a clinically palpable abscess.

Very rarely, the primary focus is beneath the posterior common ligament (fig. 2), and a few cases have been recorded (Fischer, 1919; Vincent and Darquier, 1925; Seddon, 1935) in which radiographs revealed no bony lesion until long after the onset of the paraplegia. Clinically, there is no direct way of distinguishing this type of Pott's paraplegia (what we have called the *spinal tumour syndrome*) from that due to an intraspinal neoplasm and the diagnosis can be made only by laminectomy. Almost equally rare are those cases in which the disease begins in a *neural arch* (Seddon, 1935), the abscess

[June 15, 1946]

MEETING AT WINGFIELD MORRIS ORTHOPÆDIC HOSPITAL, OXFORD

The following *short papers*, illustrated by many cases, were read as follows:

Slipped Upper Femoral Epiphysis.—Mr. W. B. FOLEY.

Treatment of Acute Osteomyelitis with Penicillin.—Mrs. AGERHOLM (for Professor J. TRUETA).

Peripheral Nerve Grafting Operation.—Professor H. J. SEDDON.

Muscle Transplantation: Portion of the Pectoralis Major Muscle to Paralysed Biceps (With Film).—Professor H. J. SEDDON.

Organization of a Regional Accident Service.—Group Captain J. C. SCOTT.

Demonstration of a Self-Propelling Surgical Chair in its Early Stage of Construction.—Mr. GIRDLESTONE.

Tendon Transplantation for Radial Paralysis.—R. B. ZACHARY, F.R.C.S.

The classical method of tendon transplantation in radial paralysis is to transfer the pronator teres tendon into the extensors of the wrist, and to use flexor carpi ulnaris and flexor carpi radialis tendons for extension of the fingers and thumb. There is no argument about the value of using the pronator teres tendon for extension of the wrist, but the transplants to the fingers and thumb are not always satisfactory. We have found that if the palmaris longus is absent the transplantation of the tendons of both wrist flexor muscles leaves nothing to control the wrist, so that when an attempt is made to extend the fingers, the wrist goes into acute dorsiflexion and the fingers remain flexed at an angle of about 40 to 60 degrees. Moreover, this action of the wrist is the reverse of the normal process, for in the normal individual there is a tendency for the wrist to come to the neutral or slightly flexed position on opening the fist. It is clear that the fault is not a technical one such as slipping of the tendons, for if the wrist is passively held in the neutral position full extension of the fingers can be achieved.

When the palmaris longus muscle is present, the results are better but still uncertain. Some patients can control the wrist fairly well with the palmaris longus but others cannot, so that in this group of cases there are still a number in which the wrist-joint tends to dorsiflex when extending the fingers, with the result that the extension of the fingers is not complete.

In those cases where the flexor carpi radialis tendon has not been used, its control of the wrist allows full extension of the fingers and, moreover, strong active flexion of the wrist is maintained. It is, therefore, our policy in tendon transplantation for cases of radial paralysis to retain the flexor carpi radialis in its normal place and to use the palmaris longus as a transplant for the thumb if it is present. If the palmaris longus is absent, we have used the flexor carpi ulnaris for the thumb as well as for the fingers with success.

[June 19, 1946]

MEETING AT ROYAL SOCIETY OF MEDICINE, 1, WIMPOLE STREET, W

Dr. Sterling Bunnell (San Francisco) gave an Address entitled *Certain Aspects Of Hand Surgery In World War II*. This was summarized in the *Lancet*, 1946 (ii), 53.

found a case in which almost the whole mass of an *intervertebral disc* had been pushed backwards and was the cause of the compression. Lastly, a vertebra riddled with tuberculous disease may suddenly *collapse like a concertina* (fig. 7), causing a paraplegia of rapid onset (Girdlestone, 1931; Butler, 1935).

FIG. 5.

FIG. 6.

FIG. 7.

FIG. 5.—Pathological dislocation of the thoracic spine causing compression of the cord. In this case the posterior common ligament was intact and the cord lesion was, therefore, purely mechanical in origin.

FIG. 6.—Radiograph of spine showing pathological dislocation. The nature of the lesion was confirmed at operation; it was also found that an abscess had penetrated the posterior common ligament—in contrast with the case shown in fig. 5, though it was doubtful whether this factor contributed to compression of the cord.

FIG. 7.—Concertina collapse of the eighth thoracic vertebral body. Diagnosis of tuberculous disease confirmed histologically. (Reproduced by permission of Mr. R. W. Butler.)

PARAPLEGIA OF LATE ONSET

In these cases the patient usually has a considerable deformity (fig. 8), he has been getting about well for a number of years after being treated for spinal caries, and then

FIG. 8.

FIG. 9.

FIG. 8.—The sort of case of old tuberculous disease of the spine in which paraplegia of late onset is not uncommon. When this photograph was taken the patient was beginning to complain of weakness of the lower limbs. A typical paraplegia developed subsequently.

FIG. 9.—The characteristic lesion in paraplegia of late onset. Although there is a bony spur in the floor of the spinal canal (a), the cause of the compression is an abscess (b), lying beneath the laminae.

compressing the cord from behind; and although radiographic changes (fig. 3) are present they have sometimes been overlooked.

FIG. 1.

FIG. 2.

FIG. 3.

FIG. 1.—Diagram showing how angulation of the spine may squeeze tuberculous material into the spinal canal.
 FIG. 2.—Spinal tumour syndrome. The patient was a woman aged 23 years who died as a direct result of the paraplegia. Although there is widespread infection of the bodies of the 4th and 5th cervical vertebrae, as shown by the loss of normal trabeculation and some erosion of the posterior surfaces of both bodies, nothing abnormal could be detected radiographically. The abscess responsible for the compression of the cord is well shown (Guy's Hospital Museum).

FIG. 3.—Radiograph of the spine of a boy aged 9 years who was admitted to hospital with incomplete paraplegia. Destructive lesion of pedicles and arch of Th. 8; a typical lesion of the vertebral bodies appeared later. (Dr. J. G. Johnstone's case, Princess Mary's Hospital, London County Council, Margate.)

Mechanical accidents.—Although a tuberculous abscess is the commonest cause of paraplegia of early onset there is a group of cases, sufficiently large to merit serious attention, in which some kind of mechanical accident has occurred as a result of the solution of continuity of the spine. The most dramatic were those cases, now very rare, in which the disease began in the atlas or axis, paralysis of all four limbs or even death occurring without any warning as a result of pathological luxation between the suboccipital vertebrae. Until the publication of our papers it was not recognized that similar though less dramatic *pathological dislocation* sometimes occurs at the usual site of disease (figs. 4, 5, and 6) producing a compression of the cord in which the tuberculous

FIG. 4.—Diagram showing the two ways in which compression of the cord may result from pathological dislocation in tuberculous disease of the thoracic spine. The shaded areas represent bone destruction: (a) the upper segment of the spine has slipped downwards and forwards (compare fig. 5); (b) the upper segment has slipped downwards and backwards (compare fig. 6). (Diagram reproduced by permission of Mr. R. W. Butler.)

disease as such may play no part whatever. We have records of a number of cases in which this state of affairs resulted from incautious laminectomy, the surgeon who removed all that was holding the vertebral column together having neglected adequate post-operative fixation. Similarly the retropulsion of a *sequestrum* may compress the cord (Sorrel and Sorrel-Déjerine, 1932; Calvé—see Butler, 1935), and five years ago I even

found a case in which almost the whole mass of an *intervertebral disc* had been pushed backwards and was the cause of the compression. Lastly, a vertebra riddled with tuberculous disease may suddenly collapse like a concertina (fig. 7), causing a paraplegia of rapid onset (Girdlestone, 1931; Butler, 1935).

PARAPLEGIA OF LATE ONSET

In these cases the patient usually has a considerable deformity (fig. 8), he has been getting about well for a number of years after being treated for spinal caries, and then

FIG. 8.

FIG. 9.

FIG. 8.—The sort of case of old tuberculous disease of the spine in which paraplegia of late onset is not uncommon. When this photograph was taken the patient was beginning to complain of weakness of the lower limbs. A typical paraplegia developed subsequently.

FIG. 9.—The characteristic lesion in paraplegia of late onset. Although there is a bony spur in the floor of the spinal canal (a), the cause of the compression is an abscess (b), lying beneath the laminae.

complains of some difficulty in walking. At first I thought that this late paraplegia was somewhat akin to traumatic ulnar neuritis; in this I was supported by the findings in a case (Seddon, 1935) in which there was undoubtedly stretching of the cord over a bony prominence in the floor of the spinal canal, and this case was cured by removal of the spur. Sorrel-Déjerine reports a similar case but there is now no longer any doubt in my mind that Butler is right in attributing most of these late paraplegias to reactivation of a small tuberculous mass inside the spinal canal. The environment of the cord is not a happy one, its circulation must be precarious, and very little compression will be required to interrupt its conductivity. A typical example is shown in fig. 9.

Two points in favour of Butler's hypothesis and against mine are that a paraplegia of late onset not infrequently clears up with rest in the same way as an early paraplegia due to compression by an abscess. And in some intractable cases on which I have operated I found the tuberculous focus which he described, and recovery followed its removal although no attempt was made to remove the bony ridge in the floor of the spinal canal.

The question of pachymeningitis is deliberately left to the last. Anyone familiar with the morbid anatomy of paraplegia of early onset must have been impressed by the remarkable appearance of the dura mater in many of the cases. Its thickness is greatly increased and the outer surface presents the typical shaggy appearance of tuberculous granulation tissue. But it has long been known that the tuberculous material may be dissected off the dura with remarkable ease (fig. 10), leaving behind a clean fibrous

FIG. 10.—Paraplegia of early onset due to compression by an abscess. The tuberculous process, shown below, has not invaded the dura, shown above, and there is even a line of cleavage visible between the two strata of tissue. (Reproduced by permission of Mr. R. W. Butler.)

membrane which seems to possess the most astonishing powers of resistance to tuberculous infection. Clearly then this is not pachymeningitis; nothing less than an interstitial tuberculous infection of the dura merits the term. With one notable exception

all recent observers are sceptical about tuberculous pachymeningitis; but the exception must be examined with care since Sorrel-Déjerine bases her classification of Pott's paraplegia on the assumption that pachymeningitis is constantly found in those cases in which the onset is late and insidious. This assumption rests on the observation of two undoubted cases of pachymeningitis. In one the cord was compressed by a bony spur opposite which was a patch of pachymeningitis; in the other, there was an anterior subluxation of the fifth cervical vertebra with consequent deformation of the cord, and an old abscess firmly adherent to the dura, the outer layers of which were infiltrated by the disease, the inner layers and internal surface being entirely normal. Although no one examining the evidence can deny that these are cases of genuine tuberculous pachymeningitis, it must be clear that in the presence of the other conditions mentioned there are hardly sufficient grounds for saying that the pachymeningitis was the cause of the paraplegia. That both these patients developed paraplegia late in the course of the disease and showed among other things patches of pachymeningitis is no proof whatever that the cord lesion was due to the tuberculous involvement of the dura mater. The condition is one that neither Butler nor I have seen.

It has been supposed that the dense fibrosis and annular constrictions of the dura sometimes found associated with paraplegia of late onset represent the healed stage of pachymeningitis. Yet there is no reason why these conditions should not result from the healing of an abscess that has been in contact with or even encircling the cord. Macewen (1888) and others who have performed laminectomy in such cases were able to strip off the fibrous tissue without opening the dura and so relieve the compression, further evidence in support of the generally accepted view that the tuberculous process is essentially epidural. The conclusion is that pachymeningitis is a very rare condition and its causal relations to paraplegia have not yet been established.

CHANGES IN THE SPINAL CORD

It must be conceded that paraplegia of early onset can occur in the absence of compression. This was demonstrated by Butler in two cases that came to post-mortem, and in a recent case of mine quite severe paraplegia was present—which recovered spontaneously—although lumbar puncture showed no evidence of spinal block. These findings have revived interest in the theory that paraplegia may be due to oedema of the cord, though we cannot tell whether the oedema is merely the result of the hyperæmia that is found in all tissues adjacent to a tuberculous focus or to a local toxic process. In Butler's cases, to which he has allowed me to refer, there was a curious vacuolation of the white matter of the cord (fig. 11) and a higher magnification (fig. 12) suggests

FIG. 11.

FIG. 11.—Paraplegia of early onset without compression of the cord. Section at the level of the disease from a woman aged 58, with an early mid-thoracic lesion admitted to the National Hospital, London, with paraplegia of six months' duration. Tuberculous granulation tissue was present in the extradural space, but there was no mechanical compression of the cord. The appearance of vacuolation in the anterior and lateral tracts of the cord is well shown. (For this and the following illustration the writer is indebted to Dr. J. G. Greenfield and Mr. R. W. Butler.)

FIG. 12.

FIG. 12.—Higher magnification of cord shown in fig. 11. The clear circular spaces give the appearance of vacuolation and it seems that the myelin sheaths are chiefly involved, the axis cylinders persisting even where the swelling is greatest.

that it is due to some change in the myelin, which swells considerably, leaving the axon still visible but not intact, since the process leads to the ordinary ascending and descending degeneration. Nevertheless, however the derangement of the cord may start, when an abscess is the causal agent, a true mechanical compression usually develops sooner or later, in no way different from that resulting from other kinds of extradural swelling. Where there has been what I have called a mechanical accident the damage to the cord is, of course, purely mechanical too.

In one case there was no doubt that a profound and rapidly fatal tetraplegia of very rapid onset was due to thrombosis of the vessels of the cord. A youth aged 18 years developed caries of the fourth to sixth cervical vertebrae, with a large abscess in the neck. This abscess was in contact with the vertebral artery (fig. 13) which was found to be thrombosed, as were a spinal branch and the medullary vessels at the same level. There

FIG. 13.—Infective thrombosis of the vertebral artery spreading along the spinal branch and involving most of the small vessels of the corresponding segment of the cord. Transverse section through the vertebral artery and an intervertebral foramen.

was no mechanical compression of the cord. This type of lesion may be more common than we suspect.

In considering the change in paraplegia of late onset Butler has drawn attention to the remarkable longitudinal shrinkage of the cord. Seeing that in most of these cases a number of vertebral bodies have been destroyed it might be supposed that the cord would be relatively too long for the spinal canal and that even the nerve roots would not bind it firmly to the anterior wall. Yet we find that the cord is always closely applied to the bony spur which is why I thought at first that we were dealing with a true bony compression. I am bound to agree with Butler that there is a widespread change in the cord which, for want of a better term, he has called atrophy, though we know nothing of its precise nature.

From the therapeutic standpoint the problem is to know what degree and duration of compression the cord can tolerate before serious permanent changes occur. We know that many cases of paraplegia recover spontaneously because the abscess shrinks as the tuberculous process becomes quiescent; furthermore there are weighty reasons why extensive operative decompression is less desirable than in other forms of cord compression. Yet an expectant policy can be carried too far. Charcot (1880) examined the cord from a case in which the patient had recovered from a paraplegia two years before he died from hip disease, and at the level of the lesion found that it was reduced to about one-third of its normal diameter, that there was extensive gliosis and obvious ascending and descending degeneration. Kröger (1888) describes another less striking case in which the only abnormality at the level of the lesion was thickening of the walls of blood-

vessels. A third case (fig. 14) I saw myself. She was treated conservatively, and after her death from amyloid disease Dr. Greenfield examined the cord. The changes seen were much the same as those described by Charcot and—it will be noted with interest—there was considerable epidural fibrosis. We cannot be satisfied with results of this kind. The truth of the matter was that the patient still had a mild paraplegia—recovery was only relative—and the condition of her cord was so precarious that a recrudescence

FIG. 14a.

FIG. 14b.

FIG. 14c.

FIG. 14.—The cord from a patient regarded as having recovered from paraplegia of early onset, the treatment having been conservative throughout. (a) Transverse section of the cervical cord showing widespread ascending degeneration especially in the columns of Goll. (b) Transverse section through the upper lumbar cord showing extensive descending degeneration in the lateral columns. (c) All that was left of the cord at the level of the lesion Th. 4-6. The cord was reduced to one-quarter of its normal cross-section area, all trace of the normal arrangement of white and grey matter has disappeared, and the number of myelinated fibres, stained black, traversing the zone is very small. The amorphous material surrounding the cord is mostly fibrous tissue.

of compression might have finished it off completely. This, I think was an example of conservatism carried too far.

In paraplegia of early onset the relation of the pathological state with the diagnosis and appropriate treatment may be summarized as follows:

Abscess.—		Diagnosis		Treatment	
Usual type	...	no difficulty	...	conservative: if severe, decompression	laminectomy laminectomy
posterior spinal disease		
spinal tumour	...	accidental	...		
Mechanical accidents.—					
subluxation	...	difficult	...	decompression essential	
sequesterum		
prolapsed disc	...	impossible	...		
concertina collapse	...	rapid onset of paralysis characteristic radiographic appearance	...	decompression may be of value	
		
Thrombosis		rapid onset of paralysis with only the usual radiographic changes	...	useless	
		

that it is due to some change in the myelin, which swells considerably, leaving the axon still visible but not intact, since the process leads to the ordinary ascending and descending degeneration. Nevertheless, however the derangement of the cord may start, when an abscess is the causal agent, a true mechanical compression usually develops sooner or later, in no way different from that resulting from other kinds of extradural swelling. Mechanical accidents.—					
subluxation	...	difficult	impossible	decompression essential	
sequestrum	...				
prolapsed disc	...				
concernina collapse	...	rapid onset of paralysis characteristic radiographic appearance	rapid onset of paralysis with only the usual radiographic changes	decompression may be of value	
	...				
	...				
Thrombosis				useless	

From the therapeutic standpoint the figures from Butler's and my series give a rough idea of the relative sizes of the three main groups of cases. The incidence of paraplegia in the 186 cases was 193, several patients suffering more than one attack of paralysis. There were 76 cases of paraplegia (39%) of early onset in which spontaneous recovery occurred, the causal factor in most of them being almost certainly an abscess. There were 21 cases (11%) in which a paraplegia of early onset failed to clear up; this number included all those cases in which the paraplegia was due to some sort of mechanical accident, and probably a few in which the cause was an abscess, early evacuation of which would have led to recovery. In no less than 96 cases (50%) the paraplegia was of late onset; in well over half (58 out of 96) recovery occurred spontaneously.

Mr. George L. Alexander: Neurological complications of spinal tuberculosis.—This communication is concerned chiefly with some aspects of the surgical management of spinal tuberculosis complicated by compression of the spinal cord, and describes some recent experiences in the treatment of such cases. A preliminary report on the technique and early results of an operation which provides an anterior decompression of the theca is included. This operation was developed largely by Mr. Norman Dott.

Skull traction has now an established place in the treatment of cervical fracture-dislocations and is replacing the irksome and less efficient chin-halter. This form of skeletal traction has an application also in the management of tuberculous disease of the cervical and upper thoracic vertebrae.

SPONTANEOUS ATLANTO-AXIAL SUBLUXATION

The following case provided the first opportunity in our series of using skeletal traction.

Female, aged 30. Two years' history of fleeting pain in upper limbs, and later, periods of pain and stiffness in the upper part of the neck. Soon she was liable periodically to attacks of momentary rigidity in all four limbs, culminating in an episode of sudden yielding of deep structures at a moment of full-flexion of the neck. Within a few hours the left greater occipital nerve field went numb. A posterior plaster shell was applied. A week later paresis of limbs on left side appeared and she was referred to our Unit.

On examination, she presented the picture of a spastic left hemiparesis, with atrophy of the small muscles of the hand, a right hemi-analgesia and thermohypæsthesia—indicating impaired conduction in the left spinothalamic tract—and proprioceptive loss distally in the limbs, more marked on the left side. X-ray films showed that the tip of the odontoid process was in contact with the posterior arch of the atlas and that the displacement had also been fortunately off to one side, so that the odontoid had gradually slipped forwards and to the left and was indenting the left lateral aspect of the cord. This asymmetrical luxation was later proved to be due to yielding of the atlanto-axial articulation on the left side only, due to a tuberculous synovitis. The corresponding joint on the right side was healthy and had stood firm. The lateral view showed a small focus of osseous tuberculosis anteriorly in the body of the axis.

The Blackburn skull traction apparatus (made of stainless steel) was applied to the patient in her posterior shell, with a pull of 9 lb. increased to 13 lb. Successive layers of thick felt were built up between the patient's neck and the shell so as to promote an anterior re-position of the cervical-spinal column relative to the skull and atlas. Within ten days reduction was complete and neurological recovery well under way.

The reduction now had to be made secure and this was achieved by exposing the arch of the atlas and lashing it with ties of thick braided silk to the spine and also the laminae of the axis, the direction of pull on the atlas being thus down and backwards, as desired. An occipito-atlanto-axial fusion was secured by grafts of split rib so disposed as to provide a reasonably secure buttress posteriorly, when consolidated.

The natural curvature of rib conformed well to this part of the skeleton.

At present this patient is again becoming ambulant about a year after the stabilizing operation and should soon be able to return to work.

CERVICO-DORSAL POTT'S DISEASE

Skeletal traction has been efficacious in the two cases of Pott's disease at this level which have so far come under our care.

Two girls, both aged 4½ years, were referred simultaneously nine months ago by reason of increasing spastic paraparesis, and in one of the little girls paresis and wasting of the small muscles of the hands had also developed. There was proprioceptive loss in the lower limbs and exteroceptive sensory depression up to an appropriate level. Lumbar manometry showed a complete block. This evidence of implication of the cord had appeared in spite of apparently satisfactory immobilization in plaster shells. Within a week of application of skull traction retrogression of the neurological abnormalities was under way and now only diminishing traces of the pyramidal lesion remain. The cervico-dorsal kyphosis has also diminished very considerably.

The patients were nursed in the posterior shells and anterior shells were available for turning so that regular attention could be given to the skin of the back. The devices

FIG. 1.—Posterior plaster shell, carrying post for attachment of skull-traction appliance.

FIG. 2.—Anterior shell applied preparatory to turning; skull-traction transferred to post on anterior shell.

FIG. 3.—Detail of the detachable posts and rubber tubes to prevent foot-drop while preserving a range of movement.

FIG. 4.—The shaded area represents the approximate extent of bone removed. On right, schematic representation of the conditions found at operation.

adopted to ensure maintenance of the skull traction during turning, and to control foot-drop merit description (figs. 1, 2 and 3). A bent strip of iron, conforming to the contour of the head end of the shells was incorporated in the plaster, bearing a 5/16 in. round rod projecting from it at a point in relation to the vertex of the skull. Thus each shell had a sort of "proboscis" about 9 in. long to which the elastic tension of the skull traction apparatus (about 3 lb. for those small persons) could be attached. We thought it important not to relax the tension on the skull, even during the periodical turning for skin toilet purposes. It was well that we did so for the pins of the traction appliance gradually worked oval holes in the thin calvaria on each side and if the tension had been relaxed the pins would have slipped out of position. The shells were, of course, kept slightly tilted so as to provide a counter-pull by the body-weight. The skull-traction was maintained continuously for four months.

Foot-drop was controlled by firm-soled felt shoes to which light rubber tubing was attached on each side. The rubber tubing was fixed detachably to a pair of upright posts housed in metal sockets incorporated in the plaster at the level of the knee, and the tension of the rubber could be adjusted at will by a metal sleeve and pinch screw. The upright posts were, of course, removable so that the anterior shell could be applied as requisite. Thus foot-drop was prevented without restricting movement at the ankle.

THORACIC POTT'S DISEASE

The neurological picture in cases with implication of the cord at this level is rather stereotyped and characteristic: the motor loss is so gross compared with the commonly slight and restricted exteroceptive depression. Proprioception, however, is early impaired, so that complete loss of joint sense is to be found disto-proximally, perhaps as high as the hips, at the stage when the surgeon is asked to intervene. Urinary retention tends to occur late, though direct questioning often elicits a long history of recurrent phases of slight difficulty of micturition.

With regard to treatment, the well-established conservative measures for the management of thoracic Pott's disease serve well for the majority of cases. My attention is directed

From the therapeutic standpoint the figures from Butler's and my series give a rough idea of the relative sizes of the three main groups of cases. The incidence of paraplegia in the 186 cases was 193, several patients suffering more than one attack of paralysis. There were 76 cases of paraplegia (39%) of early onset in which spontaneous recovery occurred, the causal factor in most of them being almost certainly an abscess. There were 21 cases (11%) in which a paraplegia of early onset failed to clear up; this number included all those cases in which the paraplegia was due to some sort of mechanical accident, and probably a few in which the cause was an abscess, early evacuation of which would have led to recovery. In no less than 96 cases (50%) the paraplegia was of late onset; in well over half (58 out of 96) recovery occurred spontaneously.

SPONTANEOUS ATLANTO-AXIAL SUBLUXATION

The following case provided the first opportunity in our series of using skeletal traction.

Female, aged 30. Two years' history of fleeing pain in upper limbs, and later, periods of pain and stiffness in the upper part of the neck. Soon she was liable periodically to attacks of momentary rigidity in all four limbs, culminating in an episode of sudden yielding of deep structures at a moment of full flexion of the neck. Within a few hours the left greater occipital nerve field went numb. A posterior plaster shell was applied. A week later paresis of limbs on left side appeared and she was referred to our Unit.

On examination, she presented the picture of a spastic left hemiparesis, with atrophy of the small muscles of the hand, a right hemi-analgesia and thermohypæsthesia—indicating impaired conduction in the left spinothalamic tract—and proprioceptive loss distally in the limbs, more marked on the left side. X-ray films showed that the tip of the odontoid process was in contact with the posterior arch of the atlas and that the displacement had also been fortunately off to one side, so that the odontoid had gradually slipped forwards and to the left and was indenting the left lateral aspect of the cord. This asymmetrical luxation was later proved to be due to yielding of the atlanto-axial articulation on the left side only, due to a tuberculous synovitis. The corresponding joint on the right side was healthy and had stood firm. The lateral view showed a small focus of osseous tuberculosis anteriorly in the body of the axis.

The Blackburn skull traction apparatus (made of stainless steel) was applied to the patient in her posterior shell, with a pull of 9 lb. increased to 13 lb. Successive layers of thick felt were built up between the patient's neck and the shell so as to promote an anterior re-position of the cervical-spinal column relative to the skull and atlas. Within ten days reduction was complete and neurological recovery well under way.

The reduction now had to be made secure and this was achieved by exposing the arch of the atlas and lashing it with ties of thick braided silk to the spine and also the laminae of the axis, the direction of pull on the atlas being thus down and backwards, as desired. An occipito-atlanto-axial fusion was secured by grafts of split rib so disposed as to provide a reasonably secure buttress posteriorly, when consolidated.

The natural curvature of rib conformed well to this part of the skeleton.

At present this patient is again becoming ambulant about a year after the stabilizing operation and should soon be able to return to work.

CERVICO-DORSAL POTT'S DISEASE

Skeletal traction has been efficacious in the two cases of Pott's disease at this level which have so far come under our care.

Two girls, both aged 4½ years, were referred simultaneously nine months ago by reason of increasing spastic paraparesis, and in one of the little girls paresis and wasting of the small muscles of the hands had also developed. There was proprioceptive loss in the lower limbs and exteroceptive sensory depression up to an appropriate level. Lumbar manometry showed a complete block. This evidence of implication of the cord had appeared in spite of apparently satisfactory immobilization in plaster shells. Within a week of application of skull traction retrogression of the neurological abnormalities was under way and now only diminishing traces of the pyramidal lesion remain. The cervico-dorsal kyphosis has also diminished very considerably.

The patients were nursed in the posterior shells and anterior shells were available for turning so that regular attention could be given to the skin of the back. The devices

FIG. 1.—Posterior plaster shell, carrying post for attachment of skull-traction appliance.

FIG. 2.—Anterior shell applied preparatory to turning; skull-traction transferred to post on anterior shell.

FIG. 3.—Detail of the detachable posts and rubber tubes to prevent foot-drop while preserving a range of movement.

FIG. 4.—The shaded area represents the approximate extent of bone removed. On right, schematic representation of the conditions found at operation.

adopted to ensure maintenance of the skull traction during turning, and to control foot-drop merit description (figs. 1, 2 and 3). A bent strip of iron, conforming to the contour of the head end of the shells was incorporated in the plaster, bearing a 5/16 in. round rod projecting from it at a point in relation to the vertex of the skull. Thus each shell had a sort of "proboscis" about 9 in. long to which the elastic tension of the skull traction apparatus (about 3 lb. for those small persons) could be attached. We thought it important not to relax the tension on the skull, even during the periodical turning for skin toilet purposes. It was well that we did so for the pins of the traction appliance gradually worked oval holes in the thin calvaria on each side and if the tension had been relaxed the pins would have slipped out of position. The shells were, of course, kept slightly tilted so as to provide a counter-pull by the body-weight. The skull-traction was maintained continuously for four months.

Foot-drop was controlled by firm-soled felt shoes to which light rubber tubing was attached on each side. The rubber tubing was fixed detachably to a pair of upright posts housed in metal sockets incorporated in the plaster at the level of the knee, and the tension of the rubber could be adjusted at will by a metal sleeve and pinch screw. The upright posts were, of course, removable so that the anterior shell could be applied as requisite. Thus foot-drop was prevented without restricting movement at the ankle.

THORACIC POTT'S DISEASE

The neurological picture in cases with implication of the cord at this level is rather stereotyped and characteristic: the motor loss is so gross compared with the commonly slight and restricted exteroceptive depression. Proprioception, however, is early impaired, so that complete loss of joint sense is to be found disto-proximally, perhaps as high as the hips, at the stage when the surgeon is asked to intervene. Urinary retention tends to occur late, though direct questioning often elicits a long history of recurrent phases of slight difficulty of micturition.

With regard to treatment, the well-established conservative measures for the management of thoracic Pott's disease serve well for the majority of cases. My attention is directed

to the case in which neurological deterioration appears acutely, or is advancing in spite of adequate immobilization. It will no doubt be conceded generally that laminectomy alone is unsatisfactory except in those rather rare cases showing primary implication of the laminae. The spinous processes and laminae are characteristically spared in Pott's disease or may be synostosed, and therefore laminectomy is structurally unsound. Of laminectomy with fusion I cannot speak from personal experience but in view of the findings disclosed by the anterior decompression operation, I should have some misgivings about the end-result in some at least of such cases. From the neurosurgical point of view we ought not to be satisfied with anything short of complete and early relief of pressure on the spinal cord.

Mr. Dott and I have been using a lateral approach to the diseased region in the past eighteen months, and the series to date amounts to 13 cases. This method affords an excellent visualization of the contents of the vertebral canal and has been notably revealing in regard to the morbidity anatomy. It provides access to the anterior aspect of the theca and, as will be seen, this is so important that we have called it an antero-lateral decompression. The neurological recovery following this operation has been so satisfactory and rapid that we are encouraged to persevere with it. It must be emphasized, however, that the operation is still on trial and undergoing modification.

Mr. Norman Capener has been working along the same lines, and has a small series of unpublished cases extending back as far as 1933. The first of these is referred to by Seddon (1935) in his extensive paper on Pott's paraplegia. The operation practised by Mr. Capener differs only in details from that now described.

The antero-lateral decompression operation is in large part an extensive costo-transversectomy but goes further. The skin incision is curved, commencing and terminating at the mid-line well above and below the region of the spine to be exposed, forming a crescentic flap extending three or four inches from the mid-line at the level of disease. Trapezius and/or latissimus dorsi are incised just lateral to the spinous processes, where the muscles are still relatively aponeurotic. These flat muscles are displaced laterally. The longitudinal posterior muscles are then reflected medially exposing the angles of the ribs. A generous resection of three or more ribs is made, going two or three inches lateral to the angles and as far medially as possible with rib shears. The transverse processes and neck and head of ribs are then nibbled away. Intercostal nerves are now apparent and we have found them an important guide in locating the pedicles and theca. By this stage, one is often working among diseased soft tissues and necrotic bone, with much anatomical deformity and the intercostal nerves are about the only reliable structures on which to rely.

Pedicles are removed in number sufficient to expose the lesion and theca well above and below the level of compression, by chiselling or nibbling away their outer aspects until a small sphenoidal punch can be used to complete the process.¹ The costo-vertebral facets are useful in assisting orientation in the wound. One works from relatively normal tissues in the vertebral canal towards the focus of disease, converging from above and below upon the critical level of compression. The diseased vertebral bodies are then excavated so as to ease the pressure on the theca as soon as possible, and allow dissection and withdrawal forwards of the compressing agent with the minimum of disturbance, and without causing even momentary aggravation of the indentation of the theca (fig. 4).

The theca below the gibbus shows none of the natural systolic pulsation but on removal of the compressing agent the theca falls forward and in our experience in most cases pulsation has then been evident throughout the whole length exposed. In a few cases no such pulsation reappeared although lumbar manometry after operation was satisfactory and subsequent recovery complete. At the conclusion of the operation one sees the arched theca, probably pulsating naturally, with the now lax intercostal nerves emerging in series, and disposed across the deeper part of the wound like the legs of a spider. The work on the gibbus is, of course, conducted between these nerves, retracted upwards or downwards with a loop of thread as convenient.

It will be evident that kyphosis materially assists access to the lateral aspect of the spinal column, and indeed when the gibbus is marked a full lateral view of the compressed theca is obtained at operation.

The operation is conducted on the anterior shell and we are now applying skull-traction as a preliminary step in the operation in cases with involvement of upper thoracic vertebrae. The patient is placed in the posterior shell about fifteen days after operation when wound healing is well under way. Professor Albert of Liège on a recent visit to us remarked that he has observed no ill-effect from using the posterior shell immediately after spinal

¹ADDENDUM.—A dental engine and large bur has been found of value in recent cases. The removal of pedicles can thus be effected with less risk of percussion-damage to the stretched cord. Sclerosed bone also is dealt with more effectively by a dental bur. We have used sterilized Paul's rubber tubing as a cover for the flexible cable of the engine.

operations, and that thereby hamatoma in the wound is prevented. We intend to try this in the cases with little kyphosis.

Abscesses have been found and evacuated in 11 of the 13 cases. A few of these were "dry," containing inspissated and calcified caseous debris which was scooped out with a spoon. In 7 of the patients a large paravertebral abscess containing pus was evacuated by suction, and in 2 of these a vertebral abscess communicated through a hole in the anterior common ligament with a prevertebral abscess cavity. In a few the head of one or more ribs was eroded and there was an abscess in relation to this, sometimes communicating with a paravertebral abscess. Thus it would seem that the imbricated method of approach and closure, and perhaps also the use of suction, permit evacuation of an abscess without serious risk of the wound breaking down subsequently. We have had one accident of this sort, however, in an elderly patient operated on for acute and active disease eighteen months ago; a sinus appeared at the lower end of her wound two weeks ago, where of course, the overlap of layers is minimal. Her spinal caries is advancing although she has as yet no recurrence of neurological symptoms.

In every one of the 13 cases operated on so far some gross mechanical factor was found to account for the spinal cord compression and in all instances pressure was being exerted mainly upon the anterior aspect of the theca and cord.

In 7 instances one or more intervertebral discs at the diseased level, usually at the apex of the gibbus, were displaced backwards and were grossly indenting the theca anteriorly. A sequestrum similarly displaced posteriorly was responsible in 2 cases, and in 2 others a vertebral abscess bulged backwards. In conformity with the wedge-shaped focus of disease it is natural that loose discs and sequestra should pass backwards when kyphosis has developed, and so come to lie hard up against the theca and cord. Two cases of the series, examples of "late paraplegia", were healed but presented a transverse ridge of bone indenting the theca at the level of the gibbus.

The removal of discs and sequestra is easy but healed cases are apt to present technical problems calling for patience and finesse if hard bone is to be removed without detriment to the cord. We believe that persistent discs and sequestra probably impede re-ossification in continuity at the diseased level, and if so their removal would seem a logical step. Time will provide an answer and it is quite possible that one of the standard bone-grafting procedures will later be required.

The indications for decompression of the cord in Pott's disease are we think no different from those in cord-compression from other causes. One cannot ignore the threat of irrevocable ischaemic damage to the cord in cases with severe and rapid development of the compression syndrome. This state of affairs calls for prompt action. Then there is the type of case in which the compression of the cord persists or advances in spite of adequate extension and fixation, and we think that in such cases the wait-and-see policy is questionable.

In passing I should like to sound a warning against the assumption that a good response in the lumbar manometer and low protein content in the lumbar C.S.F. are evidence against the existence of compression of the cord. It should be recognized that if the theca is flattened anteriorly fluid may find its way readily enough past the cord laterally at the level of compression. This was observed in one case in this series, and is, of course, also quite common in cervical disc-protrusion implicating the cord and in some extramedullary spinal tumours. The neurological status and progress are more important indications of what is going on within the vertebral canal.

The neurological recovery following the operation described can at times be dramatic and we have twice observed a substantial return of voluntary movement to the completely paraplegic lower limbs as early as twelve hours after operation. With one exception all cases have recovered complete or almost complete motor and sensory function. The exception refers to an adult with healed extreme kyphosis exceeding a right-angle, dating from early childhood, with paraparesis of late onset. The spinal cord was like a ribbon, stretched across a transverse ridge of bone at the apex of the gibbus. The greatest caution was exercised in avoiding disturbance of the cord, nevertheless the melancholy result has been that of a total transverse lesion. One spinal branch of an intercostal artery opposite the gibbus was damaged during exposure and it is highly probable that this was an artery of importance in the segmental supply to the cord. The lesson is obvious.

Sex and age call for no special comment in the series; the youngest patient was aged 6 years, the oldest 65 years. The two patients with a healed lesion and late paraparesis were adults in the fourth decade.

to the case in which neurological deterioration appears acutely, or is advancing in spite of adequate immobilization. It will no doubt be conceded generally that laminectomy alone is unsatisfactory except in those rather rare cases showing primary implication of the laminae. The spinous processes and laminae are characteristically spared in Pott's disease or may be synostosed, and therefore laminectomy is structurally unsound. One spinal branch of an intercostal artery opposite the gibbus was damaged during exposure and it is highly probable that this was an artery of importance in the segmental supply to the cord. The lesson is obvious.

Sex and age call for no special comment in the series; the youngest patient was aged 6 years, the oldest 65 years. The two patients with a healed lesion and late paraparesis were adults in the fourth decade.

Three of the 13 patients died, an operative mortality of 23%. They were all serious cases from the neurological point of view, with rapid onset of complete paraplegia. Two died of uremia three and four days after operation; in one of these military renal tuberculosis was found. We make it a practice now to assess renal efficiency and are unwilling to advise this rather formidable operation for the patient over 50 years of age unless the situation is one of extreme urgency. The third patient died ultimately from the effects of an unrelieved compression of the cord. This was one of the earlier cases and had a previous lateral decompression in which pedicles alone were removed, followed later by an antero-lateral decompression with approach from the opposite side. Thus pedicles were removed bilaterally and such instability resulted that intact vertebral bodies were soon over-riding. Had we been quicker in applying skull traction and in performing a stabilizing bone-graft the unfortunate outcome in this case might have been avoided. The lateral decompression was obviously ineffective and we abandoned it after this one experience. It formed, however, the link between costo-transversectomy and the antero-lateral decompression operation.

No evidence has so far been forthcoming that the operation disseminates infection. Although no clear evidence of sound re-ossification is yet to hand in this rather recent series, it can be said that the disease has not advanced, as judged radiologically, except in the case in which a sinus developed at the wound.

I am not in a position to speak from personal experience of the value of costo-transversectomy with evacuation of paravertebral abscess. Certainly that operation gives some good results and might well be considered for the case deemed unfit for the anterior decompression. In such circumstances, however, no substantial relief of pressure on the cord by say an intervertebral disc could be expected. Skull-traction would seem to have a place in the management of thoracic Pott's disease in this category, and very considerable traction and extension could be provided in the semi-sitting position, as described by McKenzie (1935) and more recently by Guthkelch (1945). We have not yet had occasion to use this method.

The following two cases are of clinical interest:

We have seen recently a boy of 12 years whose tuberculous kyphosis was precipitated quite definitely by the spasms of tetanus. Later he developed a spastic paraparesis but had recovered fully from this when we saw him. It had been thought that his rounded "juvenile kyphosis" was well ossified, and so it seemed on superficial examination of the X-ray films which came with him. Stereoscopic views showed what we had suspected, namely calcifications in a large paravertebral abscess overlying the extremely rarefied tuberculous vertebral bodies. This case exemplifies an unusual precipitating factor in the development of kyphosis in Pott's disease, and also emphasizes the value of stereoscopic X-ray films.

Another boy of 9 years, one of the anterior decompression series, exhibited a slight ataxia of one upper limb which was puzzling until we obtained films showing a large calcified tuberculoma in the cerebellum. The lesson here I suppose, is to be on the look-out for the occasional case with multiple foci of involvement of the nervous system.

A few final remarks may perhaps be permitted, as an epilogue, on a topic which though not embraced in the term paraplegia is of neurological interest in connexion with tuberculosis of the spine:

We have had two patients presenting superficially the syndrome of ruptured lumbar intervertebral disc. Both were young soldiers complaining of lumbar backache and of monoradicular type of referred sciatic pain, L5 in one case and S1 in the other. The backache dominated the picture and recurred after periods of rest more rapidly and constantly than is typical with ruptured intervertebral disc. X-ray examination disclosed a characteristic "woolliness" at one intervertebral space and localized subperiosteal erosion of adjacent anterior surface of vertebral bodies. One of the patients was operated on deliberately a year ago because of an exacerbation of the root-compression syndrome, and typical pus and tuberculous debris were evacuated from the lumbo-sacral space after the grossly bulging annulus had been incised. The root pain promptly ceased. Incidentally his progress in a sanatorium, immobilized in plaster, was giving every satisfaction when he died suddenly of a pulmonary embolus two months ago.

Pott's paraplegia presents a problem involving risk to the patient and very considerable labour on the part of medical and nursing personnel; it offers a field for improvement in management. The neurological complications of Pott's disease are often preventable and can be traced to faulty early diagnosis and to imperfections and delay in treatment when the disease has been diagnosed. One should look forward perhaps to a future in which the major operative procedure described in this paper will be of little more than historical interest.

DISCUSSION ON

LEUKÆMIA AND LEUKOSIS IN MAN AND ANIMALS

Professor J. Engelbreth-Holm: *The comparative pathology of animal leukosis.*—The comparative pathology of animal leukoses and their relationship to leukosis in man are subjects which seem perhaps even more difficult to deal with adequately to-day than appeared to be the case some years ago. We cannot, for instance, adequately define the term "leukosis" so as to exclude states similar to that morbid condition but in some ways different from it. The leukæmoid reactions in infections and intoxications occur in both man and animals. Then again, we are not sure whether the various conditions we consider to represent leukosis are all of similar nature: for instance, some of the lymphoid leukoses seem to behave differently from the more typical leukotic diseases.

Leukoses seem to me to be true malignant growths arising from the hæmopoietic tissues. They were at first believed to represent the reaction to infections and this view was then followed by the theory that they represented biologically benign hyperplasias. Our present view is that leukoses are neoplastic conditions exhibiting true autonomous growth. It is possible that certain leukotic states are due to metabolic disorders. It may well be that the leukoses include a variety of conditions of diverse origin. It would, in my view, be a valuable procedure to try to eliminate from the leukoses all conditions which do not conform to the definition "tumour growth of the blood-forming tissues". This is, however, a very difficult task.

The classification of true leukoses is itself a difficult problem. It was formerly the custom merely to classify leukosis according to the type of cell involved: myelogenous, erythroblastic, lymphogenous, monocytic or reticulocytic, and plasma cell (human pathology only). Within each of these types, however, the condition may manifest itself in different ways, displaying the features of acute or chronic leukosis which possibly are analogous to the varying stages of differentiation of the cells of malignant tumours in general. The classification into leukæmic and aleukæmic leukosis is of doubtful value.

There is some evidence from studies of leukosis in man and in the mouse which makes it doubtful whether a strict classification such as that outlined above is justifiable. For

Three of the 13 patients died, an operative mortality of 23%. They were all serious cases from the neurological point of view, with rapid onset of complete paraplegia. Two died of uræmia three and four days after operation; in one of these military renal tuberculosis was found. We make it a practice now to assess renal efficiency and are unwilling to advise this rather formidable operation for the patient over 50 years of age unless the situation is one of extreme urgency. The third patient died ultimately from the effects of an unrelieved compression of the cord. This was one of the earlier cases and had a previous lateral decompression in which pedicles alone were removed, followed later by an antero-lateral decompression with approach from the opposite side. Thus pedicles were removed bilaterally and such instability resulted that intact vertebral bodies were soon over-riding. Had we been quicker in applying skull traction and in performing a stabilizing bone-graft the unfortunate outcome in this case might have been avoided. The lateral decompression was obviously ineffective and we abandoned it after this one experience. It formed, however, the link between costo-transversectomy and the antero-lateral decompression operation.

No evidence has so far been forthcoming that the operation disseminates infection. Although no clear evidence of sound re-ossification is yet to hand in this rather recent series, it can be said that the disease has not advanced, as judged radiologically, except in the case in which a sinus developed at the wound.

I am not in a position to speak from personal experience of the value of costo-transversectomy with evacuation of paravertebral abscess. Certainly that operation gives some good results and might well be considered for the case deemed unfit for the anterior decompression. In such circumstances, however, no substantial relief of pressure on the cord by say an intervertebral disc could be expected. Skull-traction would seem to have a place in the management of thoracic Pott's disease in this category, and very considerable traction and extension could be provided in the semi-sitting position, as described by McKenzie (1935) and more recently by Guthkelch (1945). We have not yet had occasion to use this method.

The following two cases are of clinical interest:

We have seen recently a boy of 12 years whose tuberculous kyphosis was precipitated quite definitely by the spasms of tetanus. Later he developed a spastic paraparesis but had recovered fully from this when we saw him. It had been thought that his rounded "juvenile kyphosis" was well ossified, and so it seemed on superficial examination of the X-ray films which came with him. Stereoscopic views showed what we had suspected, namely calcifications in a large paravertebral abscess overlying the extremely rarefied tuberculous vertebral bodies. This case exemplifies an unusual precipitating factor in the development of kyphosis in Pott's disease, and also emphasizes the value of stereoscopic X-ray films.

Another boy of 9 years, one of the anterior decompression series, exhibited a slight ataxia of one upper limb which was puzzling until we obtained films showing a large calcified tuberculoma in the cerebellum. The lesson here I suppose, is to be on the look-out for the occasional case with multiple foci of involvement of the nervous system.

A few final remarks may perhaps be permitted, as an epilogue, on a topic which though not embraced in the term paraplegia is of neurological interest in connexion with tuberculosis of the spine:

We have had two patients presenting superficially the syndrome of ruptured lumbar intervertebral disc. Both were young soldiers complaining of lumbar backache and of monoradicular type of referred sciatic pain, L5 in one case and S1 in the other. The backache dominated the picture and recurred after periods of rest more rapidly and constantly than is typical with ruptured intervertebral disc. X-ray examination disclosed a characteristic "woolliness" at one intervertebral space and localized superiosteal erosion of adjacent anterior surface of vertebral bodies. One of the patients was operated on deliberately a year ago because of an exacerbation of the root-compression syndrome, and typical pus and tuberculous debris were evacuated from the lumbo-sacral space after the grossly bulging annulus had been incised. The root pain promptly ceased. Incidentally his progress in a sanatorium, immobilized in plaster, was giving every satisfaction when he died suddenly of a pulmonary embolus two months ago.

Pott's paraplegia presents a problem involving risk to the patient and very considerable labour on the part of medical and nursing personnel; it offers a field for improvement in management. The neurological complications of Pott's disease are often preventable and can be traced to faulty early diagnosis and to imperfections and delay in treatment when the disease has been diagnosed. One should look forward perhaps to a future in which the major operative procedure described in this paper will be of little more than historical interest.

Turning now to lymphogenous leukaemia in man we find a confused picture—acute and chronic, leukaemic and aleukaemic with diffuse leukotic changes, and cases displaying more or less localized sarcomatous infiltrations. All are grouped together as lymphogenous leukaemia. In 1942 Bethell and Wiseman, working independently, published evidence to show that chronic small round-cell leukemia (the distinctive cells being well-differentiated lymphocytes) is a distinct entity. The condition occurs mainly in elderly men. Wiseman considers it to be neither neoplastic nor infectious, but possibly metabolic. The disease has some similarities to bovine leukosis. Bethell distinguishes three forms of the human disease: lymphoblastic leukosis which is a disease of childhood, lymphosarcoma-cell leukosis which is a distinct morphological and clinical entity occurring at any age, and lymphocytic leukosis which is relatively benign and is seen mainly in middle-aged and elderly people. The three types can be readily distinguished by smear preparations, but not in sections. It is not yet possible to decide whether we have here three distinct diseases or whether we are dealing with different stages of differentiation of the same cell-type and thus with three stages of the same tumour.

Lymphosarcoma-cell leukosis in man bears a striking resemblance to the majority of mouse leukoses, whereas the chronic benign lymphocytic leukosis of man is seldom if ever seen in rodents but is very similar to leukosis of cattle and to non-transmissible fowl leukosis. The combined sarcoma leukosis strain of fowls described by Furth seems to be analogous to the lymphoblastic leukosis of Bethell and to lymphosarcoma-cell leukosis. A disease corresponding to neurolymphomatosis of fowls has not so far been observed in other animals.

I have tried, so far, to analyse the morbid pictures included in the term leukosis and have shown that it is likely that some of them appear not to belong to the true neoplastic leukoses. Let us now consider the relationship between true leukosis in man and animals. The fully developed picture as regards both myelogenous and lymphogenous forms of leukosis is the same in man and animals. The occurrence of certain distinct conditions, such as erythroblastic leukosis in fowls and myelomatosis in man does not invalidate the general similarity. The former disease is probably to be explained on a basis of the difference in the erythropoietic mechanism in birds and mammals. In my view the erythrocytes of the fowl are less differentiated than those of mammals and thus more prone to neoplastic transformation. Furthermore, malignant erythroblastosis combined with myelogenous leukosis is not unknown in man. So far as I know no disease corresponding to neurolymphomatosis of fowls occurs in man. We do not know why plasma-cell leukosis and myelomatosis, apart from an isolated observation by Furth in mice, do not occur in animals.

In general it is clear that a study of leukosis in animals contributes much of value to our understanding of the condition in man. This applies, however, only to spontaneous leukosis; transplanted leukosis is essentially different. In my laboratory we have been able to cure transplanted mouse leukosis by intravenous injection of carcinogenic hydrocarbons, whereas the same treatment has been without effect on the spontaneous disease. A few cases in man treated in the same way have shown some improvement but not complete recovery.

Not infrequently it is found that in mouse leukosis the starting point of the lesions is in the thymus and McEndy, Boon and Furth have shown that surgical removal of the thymus in mice will lower the incidence of leukosis from about 70% to as low as 10%. Experiments carried out by Rask-Nielsen in my laboratory and, as yet incomplete, have confirmed this observation to some extent in that they have shown that the thymus is more sensitive than other tissues to the action of carcinogenic hydrocarbons. It is not yet clear whether these cases of mouse leukosis are analogous only to those human cases in which thymus tumours occur—a rare finding—or whether the difference is merely accidental. It is true to state that mouse leukosis is very similar to human leukosis, provided that under the latter we consider only stem-cell leukosis and markedly neoplastic sarcomatous forms.

One can conclude that leukosis depends on the genetic constitution of the organism, a fact which stands out very clearly from work on the mouse and also from Dr. Videbæk's observations in man. Whether the influence of hormones and of caloric restriction is as marked in human leukosis as has been found in the mouse is not known, but it is known that in both species there occurs acceleration of leukosis in predisposed individuals by exogenous carcinogens. This has been shown in mouse leukosis for X-rays and carcinogenic hydrocarbons and in man for X-rays and radium. Attempts to cure mouse leukosis with the aim of finding suitable methods for human leukosis should be undertaken but the work should be carried out with the spontaneous disease since results with the transplanted disease in the mouse will be of more doubtful value.

example, lymphogenous and myeloid leukaemia seem to be associated with the same genetic factor. Thus in inbred mouse strains the two forms of leukaemia may occur, the lymphogenous form usually predominating. Investigations made by Dr. Videbæk and not yet published (Danish Cancer Registry) have shown that among the families of 211 leukaemic patients leukaemia has been traced in other members of 17 of them, i.e. 8%. All types of leukaemia were represented and in the same relative proportion as in groups of non-selected leukaemia cases. Contrary to previous observations, different forms of the disease may occur in the same family. The age incidence seems to differ in this series from what is found in unselected material; the average age for leukaemia cases being 44 years, as compared with 50 years among 310 cases from Danish hospitals during recent years. This evidence suggests that, as in the mouse, genetic factors are of importance in the development of human leukaemia, and also that different forms of leukaemia may develop under the influence of the same genetic factor.

In spite of these reservations it is nevertheless advisable to treat each form of leukaemia separately, especially if we are to distinguish true leukaemia from allied morbid states of doubtful origin.

First, let us consider myelogenous leukaemia. This occurs in man, the mouse, the fowl, and the rat. It has not been described for certain in other animals. The chronic myelogenous leukaemias are essentially similar in the different species but there occurs a variety of atypical conditions of doubtful nature. It is often difficult to differentiate a leukaemoid state from a true leukaemia. In mice, the distinction can now be fairly easily made since definite criteria have been laid down. In man, however, the problem is more difficult and many cases are reported as leukaemia which are in fact non-specific reactions of the myeloid tissue, and others are cases of myelosclerosis.

When we come to lymphogenous leukaemia we find the difficulties are even greater, not so much in the recognition of leukaemoid reactions, although these do occur, but for other reasons. Lymphogenous leukaemia is known in man and in many animal species. Special interest attaches to this form of leukaemia in fowls, mice and cattle; the disease has not been seriously studied in other animal species. We first began to doubt the strictness of the identity of leukaemia when it was established that the condition in the fowl is not transmissible whereas the myelogenous and erythroblastic forms are readily transmitted. No evidence was obtained that the lymphogenous form was caused by a virus until more recently work by Furth established that a virus could produce a very immature lymphoblastic leukaemia. The numerous publications dealing with neuro-lymphomatosis in the fowl still further complicate the picture in this species. This disease, although resembling malignant proliferation of lymphoid cells in some respects, nevertheless presents certain very important differences—the condition of the marrow and the occurrence of paralysis. We thus seem to have three morbid states in the fowl, all associated with neoplastic proliferation of lymphogenous cells.

In cattle, German workers have described a disease which they call lymphogenous leukaemia and which resembles in its morphology the lymphogenous leukaemias of other animals and man and is associated with diffuse infiltrations of relatively well-differentiated lymphocytes. It is odd, however, that the disease has never yet been successfully transmitted to normal animals. It is furthermore very striking that those who have studied the aetiology of the disease have concluded that the causal factor must be sought in the soil, the food, or in metabolic derangements. There seems to be a hereditary factor but no one has ever regarded the disease as a malignant tumour. During the war years nothing has been seen of further investigations of the disease in Germany. In 1942 Egebjerg published an article in Denmark in which he failed to find any relationship between the occurrence of the disease in cattle and the soil character, in contrast to suggestions from German workers. This author failed to transmit the disease. He demonstrated the presence of argentophil fibrils in the infiltrations, thus showing the morbid process to be a reticulosis and not a true lymphogenous leukaemia. In 229 of 368 cows which showed no symptoms, pathological cells similar to those occurring in the infiltrations were found in the blood but not one of the animals developed leukaemia over a period of two years. These findings make it even more doubtful whether so-called cattle leukaemia is to be considered a true leukaemia.

Lymphogenous leukaemia in the mouse has been very extensively studied. It is a transmissible malignant growth which can be accelerated by carcinogenic substances of various kinds. This disease, together with the closely-related stem-cell leukaemia, presents a well-defined morbid picture and is similar to leukaemic lymphosarcomatosis in man.

Turning now to lymphogenous leukaemia in man we find a confused picture—acute and chronic, leukæmic and aleukæmic with diffuse leukotic changes, and cases displaying more or less localized sarcomatous infiltrations. All are grouped together as lymphogenous leukaemia. In 1942 Bethell and Wiseman, working independently, published evidence to show that chronic small round-cell leukaemia (the distinctive cells being well-differentiated lymphocytes) is a distinct entity. The condition occurs mainly in elderly men. Wiseman considers it to be neither neoplastic nor infectious, but possibly metabolic. The disease has some similarities to bovine leukaemia. Bethell distinguishes three forms of the human disease: lymphoblastic leukaemia which is a disease of childhood, lymphosarcoma-cell leukaemia which is a distinct morphological and clinical entity occurring at any age, and lymphocytic leukaemia which is relatively benign and is seen mainly in middle-aged and elderly people. The three types can be readily distinguished by smear preparations, but not in sections. It is not yet possible to decide whether we have here three distinct diseases or whether we are dealing with different stages of differentiation of the same cell-type and thus with three stages of the same tumour.

Lymphosarcoma-cell leukaemia in man bears a striking resemblance to the majority of mouse leukoses, whereas the chronic benign lymphocytic leukaemia of man is seldom if ever seen in rodents but is very similar to leukaemia of cattle and to non-transmissible fowl leukaemia. The combined sarcoma leukaemia strain of fowls described by Furth seems to be analogous to the lymphoblastic leukaemia of Bethell and to lymphosarcoma-cell leukaemia. A disease corresponding to neurolymphomatosis of fowls has not so far been observed in other animals.

I have tried, so far, to analyse the morbid pictures included in the term leukaemia and have shown that it is likely that some of them appear not to belong to the true neoplastic leukoses. Let us now consider the relationship between true leukaemia in man and animals. The fully developed picture as regards both myelogenous and lymphogenous forms of leukaemia is the same in man and animals. The occurrence of certain distinct conditions, such as erythroblastic leukaemia in fowls and myelomatosis in man does not invalidate the general similarity. The former disease is probably to be explained on a basis of the difference in the erythropoietic mechanism in birds and mammals. Lymphogenous leukaemia in the mouse has been very extensively studied. It is a transmissible malignant growth which can be accelerated by carcinogenic substances of various kinds. This disease, together with the closely-related stem-cell leukaemia, presents a well-defined morbid picture and is similar to leukaemic lymphosarcomatosis in man.

any positive evidence that this is the explanation of the difference in behaviour between susceptible fowls.

For practical purposes we can regard this group of diseases as particularly contagious during early life and affecting principally fowls of certain breeding. Studies on avian leukaemia may also produce information of comparative interest. For instance, the observation by Asplin (1941) that the acute chick disease produced by the agent recovered from neurolymphomatosis is curable by sulphonamide drugs indicates that chemotherapeutic measures should be explored in all diseases of this kind.

Dr. E. G. White: *Leukæmia in the dog*.—This disease has been known to veterinarians for many years as Hodgkin's or Pseudo-Hodgkin's disease, although it is quite different from the disease in man. The condition is characterized by great enlargement of the lymph nodes and nearly always of the spleen, and by leukæmic infiltration of various other organs and tissues. A recent detailed study of the disease in the United States (Bloom, F., and Meyer, L. M., 1945, *Amer. J. Path.*, 21, 683-715), which included examination of the peripheral blood and bone-marrow biopsy, suggests the term "malignant lymphoma" for the disease and classifies it, according to the type of malignant cell, as lymphoblastic, lymphosarcoma-cell, mixed-cell, and lymphocytic.

Among 512 dogs coming to us for autopsy during 1938-39 the incidence was 1.8%. The incidence among dogs coming to clinics is about 0.1—0.3%. Only 2 of 44 cases occurred in animals under 3 years old, and the highest incidence was between 4 and 8 years. Although a total of 21 breeds were represented in the series there were 10 cases in Aberdeen Terriers and it is of interest that the incidence in this breed was high in the series examined by the American workers quoted above. The clinical history was of enlargement of the lymph nodes of the throat and neck for one to four weeks before admission. All the animals had either died or had been destroyed *in extremis* within nine weeks of admission. Considerably longer periods of survival have been recorded in the literature, however. Almost all the lymph nodes are eventually grossly enlarged, the spleen is readily palpated, there is often diarrhoea and sometimes a cough, and wasting is considerable. Enlargement of the lymph nodes of the throat may cause local œdema and this was sometimes the reason for having the animal destroyed.

The blood shows anæmia and usually a high leucocyte count but the latter is mainly due to an excess of neutrophil leucocytes, including many non-segmented cells and occasional myelocytes. The American workers consider the blood picture to indicate a neutrophil leucocytosis and in some animals they found widespread extramedullary myelopoiesis, which, in the past, has sometimes given rise to the mistaken diagnosis of myeloid leukaemia. It is doubtful whether true myeloid leukaemia has been recorded in the dog.

Three cases of the disease were treated with urethane by Mr. G. C. Knight, at Dr. Haddow's suggestion, but although there was, at first, some improvement of the general condition the lymph nodes remained enlarged and the disease later progressed as in untreated animals.

Several attempts have been made to transmit the disease, so far without success.

Dr. J. M. Alston said that as a clinical pathologist he would like to know what deductions Dr. Engelbreth-Holm made from the occurrence of aleukæmic leukaemia; did he consider that it pointed to a double failure of function in fully developed leukaemia, first an excessive production of leucocytes in the bone-marrow and then, as a separate process, the failure of the power to retain immature forms in the marrow in contrast to the retention of them which is seen in health and in most conditions of marrow proliferation such as the leucocytosis of infections? Secondly, as to the ætiology of leukaemia, did Dr. Engelbreth-Holm sympathize with the view of Gohs, who published in 1934 a suggestion that in fowls leukaemia and some forms of tumours might be due to transmissible lytic substance which can be produced from tissue cells? Gohs based his hypothesis on experiments in which he injected into fowls irradiated decomposition products from bone and bone-marrow of normal fowls and produced thereby changes resembling leukaemia or sarcoma.

To summarize the results achieved by comparative studies of the pathology of leucosis we may say that our classification is unsatisfactory. We need to separate leukaemoid reactions following infections and also myelosclerosis from the group of true leukoses. We should also consider whether we need a special group to include cattle leukosis, chronic lymphatic leukosis in aged people, and perhaps also non-transmissible lymphogenous leukosis of fowls. We have also seen that true leukoses are malignant tumours of the hæmopoietic tissues and are analogous in animals and man, and also that morphologically different types occur, due to varying genetic factors and are not to be considered as being so widely separated as hitherto.

Mr. F. Blakemore: Avian leukaemia.—This group of diseases is of enormous economic importance to the poultry industry. Ellerman's original classification of fowl leukaemia into myeloid, erythroid and lymphoid forms, has held good in principle, but a certain amount of confusion has arisen regarding the relationship between these conditions. The occurrence of lymphomatosis during recent years has complicated the position still further. There is now evidence that erythroleucosis and myeloid leukaemia are closely related (Stubbs and Furth, 1931) and they may occur as different manifestations of the same infection. The position regarding lymphatic leukaemia remains unsettled; it was originally believed to be non-transmissible but now some workers do not recognize it as a specific entity and regard it as a manifestation of lymphomatosis. It seems probable, however, that it can occur as a separate condition and some cases may arise from infection with a lymphoid tumour agent similar to that described by Olsen (1941).

There is a lack of agreement regarding the relationship between lymphomatosis, both visceral and neural, and the true leukaemic conditions. The occurrence of all forms of leukaemic disease, in groups of fowls inoculated with material from a single donor affected with lymphomatosis, has led to the so-called "unitarian theory" (Biester and Devries, 1944) which attributes them to a single virus, and classifies them together as the "leucosis complex". Further information regarding the correctness of this theory is desirable, since the evidence on which it is based is open to the criticism that experiments have not been carried out with virus-free stocks.

Neurolymphomatosis (fowl paralysis) is much more prevalent in this country than the true leukaemic conditions, which tend to be sporadic. It differs from true leukaemia in that there is no significant blood change. The lesions vary from a slight diffuse infiltration of certain organs to single or multiple lymphomatous tumours in the viscera.

The peripheral nerves are often also infiltrated although nerve lesions may be a manifestation of certain other transmissible conditions of the fowl (Furth, 1935). In a pathological sense neurolymphomatosis probably occupies an intermediate position between the inflammatory conditions and those which are characterized solely by an unrestricted autonomous proliferation of blood elements. Like the leukaemic conditions it also resembles, in some respects, the neoplastic conditions.

It is now generally agreed that avian leukaemia is due to virus infection. My own experiences have been mainly limited to the agent recovered from neuro-lymphomatosis and its properties can be summarized as follows:

(1) Neurolymphomatosis virus is much more infective to chicks than older stock; the resistance factor develops gradually and cannot be attributed to previous infection.

(2) While the natural disease is essentially chronic and rarely manifested under the age of 5 months, the virus can be raised in virulence by rapid passage through groups of chickens. In this state it causes a disease which is fatal within a few days.

(3) The rise in virulence of the lymphomatosis virus is accompanied by a marked change in the effect it produces on the tissues, the acute disease being characterized by necrosis of the capillary walls and cells in their immediate vicinity. In this respect there is a similarity between it and the Rous sarcoma virus which Duran-Reynals (1940) described as producing an acute hæmorrhagic disease in young chicks.

(4) Another point of resemblance between these two agents is the varying susceptibility of different strains of fowls to infection. Some strains of chickens are particularly resistant to the agent recovered from lymphomatosis. Only some of the susceptible strains, and certain individuals of these strains, develop proliferative lymphocytic lesions as a manifestation of chronic infection. The possibility that two agents are concerned in the aetiology of this neoplastic kind of response has been considered, since it seemed possible that the lymphomatosis virus may play the rôle of an agent exciting a second latent infection carried by certain fowls. We have been unable, however, to obtain

any positive evidence that this is the explanation of the difference in behaviour between susceptible fowls.

For practical purposes we can regard this group of diseases as particularly contagious during early life and affecting principally fowls of certain breeding. Studies on avian leukaemia may also produce information of comparative interest. For instance, the observation by Asplin (1941) that the acute chick disease produced by the agent recovered from neurolymphomatosis is curable by sulphonamide drugs indicates that chemotherapeutic measures should be explored in all diseases of this kind.

Several attempts have been made to transmit the disease, so far without success.

Dr. J. M. Alston said that as a clinical pathologist he would like to know what deductions Dr. Engelbreth-Holm made from the occurrence of aleukæmic leukaemia; did he consider that it pointed to a double failure of function in fully developed leukaemia, first an excessive production of leucocytes in the bone-marrow and then, as a separate process, the failure of the power to retain immature forms in the marrow in contrast to the retention of them which is seen in health and in most conditions of marrow proliferation such as the leucocytosis of infections? Secondly, as to the ætiology of leukaemia, did Dr. Engelbreth-Holm sympathize with the view of Gohs, who published in 1934 a suggestion that in fowls leukaemia and some forms of tumours might be due to transmissible lytic substance which can be produced from tissue cells? Gohs based his hypothesis on experiments in which he injected into fowls irradiated decomposition products from bone and bone-marrow of normal fowls and produced thereby changes resembling leukaemia or sarcoma.

Dr. R. J. Ludford raised the question whether the sensitivity of leukaemia cells was related to the frequency of mitosis. Professor A. P. Dustin had often drawn attention to the fact that the lymphoid tissues were specially sensitive to his "poisons caryoclasiques", which included a variety of chemical compounds and ionizing radiations. Then Lits, Kirschbaum and Strong reported that a rapidly growing lymphoid mouse tumour with which they worked was extremely sensitive to the mitotic poison, colchicine. Some tumours appeared to regress completely after treatment but always recurred so that the mice died ultimately of leukaemia. While it is generally true that the more rapid the growth of cells, the more readily they are injured by toxic substances, nevertheless cells of different tissues exhibit different susceptibility to poisons. There is the possibility that the relatively small mass of cytoplasm in proportion to nuclear volume renders cells of the lymphocyte type particularly sensitive to injury by physical and chemical agents.

Professor G. R. Cameron asked Professor Engelbreth-Holm whether he had any explanation for the numerous hæmorrhages which so commonly accompany the more acute forms of leukaemia. He had frequently examined such hæmorrhages by means of serial sections and was unable to come to any conclusion as to their nature. Rupture of vessels could not be established. Capillaries were most frequently a site of bleeding, and it was difficult to associate any structural change in them with the extravasations of blood.

He also inquired whether Professor Engelbreth-Holm had any information about the action of nitrogen mustards in leukaemia. Some of these compounds were water soluble, and could be made suitable for administration; in fact, some work had already been done in America. The nitrogen mustards, like the classical sulphur-containing mustard gas, have a specific destructive action on the granulocyte-forming tissue of the bone-marrow, as well as on the lymphoid tissue. It was possible to lower the white cell content of the blood by means of small doses without any grave disturbance of other tissues. The effects were temporary, however, and there was no evidence of maintained improvement. A great deal more research work needed to be done on this subject and it might be possible by means of co-operation between the chemist and the clinician, to obtain a potent compound which was safe and exerted the minimal harmful effects.

Dr. L. Foulds agreed with previous speakers about the difficulties in the diagnosis and classification of the leukoses and referred to transitional forms between typical leukoses and typical neoplasms in fowls.

Professor Engelbreth-Holm in reply to Dr. J. M. Alston: The problem of how aleukæmic leukaemia is to be understood is rather obscure. I do not think that it is necessary to assume a double failure of function. We have to wait for further information whether the suggestion of Rohr is right. Rohr is of the opinion that aleukæmic leukaemia occurs when the leukaemic processes are restricted to the bone-marrow, whereas the leukaemic picture will only develop in those cases where leukaemic processes are found outside the skeleton (spleen, liver, &c.). I am not convinced myself that this suggestion is correct, but Dr. C. Johansen in Copenhagen, in an exclusive work not yet published, thinks that Rohr is right.

As to the ætiology of leukaemia the view of Gohs was put forward by Dr. Rothe Meyer and myself in 1933. "The lytic substance" is obviously nothing but the virus in fowl leukaemia and this hypothesis only concerns fowl leukaemia and Rous sarcoma.

In reply to Professor G. R. Cameron: The explanation for the hæmorrhages is, I should think, thrombopenia. The hæmorrhages are first of all seen in cases of stem-cell leukaemia and lymphogenous leukaemia, where thrombopenia is marked, whereas they are lacking in myelogenous leukaemia in which the number of thrombocytes is normal or even increased.

I have no experience of the action of nitrogen mustard.

The Female Urethra and its Relation to Upper Urinary Tract Infections. [*Abridged*]

By HOWARD G. HANLEY, M.D., F.R.C.S.

THE main purpose of this paper is to attempt to demonstrate the close relationship between urethral inflammation and upper urinary tract infection in women of the child-bearing age.

Over half of the women attending my genito-urinary clinic have symptoms directly referable to the urethra and I find it difficult to explain the general lack of attention shown to this organ in this country. The standard British textbooks of medicine, surgery and gynaecology hardly mention inflammatory lesions in the female urethra other than caruncles or gonorrhœa; not that the symptoms of frequency, urgency and dysuria, are neglected, far from it, but they are generally ascribed to cystitis which I contend is a relatively rare condition compared with the urethro-trigonitis which really causes these symptoms. The work and papers of Folsom in 1931, and later of Stevens (1935) and Bugbee (1917) and many others have received recognition in America, and the fact that the female urethra is a common source of symptoms is accepted in that country, but here in England apart from the late Frank Kidd, Winsbury-White (1933*a*) has been a voice crying in the wilderness on this subject for many years.

Two simple groups of inflammation can occur in the female urethra—the purulent and the non-purulent. The purulent form is commonly, but not only, due to the gonococcus and is recognized by everyone; but the non-purulent type, particularly if associated with a normal urine as frequently happens, is not only seldom diagnosed but its existence is even denied by some surgeons.

It is this non-purulent urethritis, or, as it is sometimes called, granular-urethritis or cystalgia (Ormond, 1935) with which I am concerned here.

The pathology is really a urethro-trigonitis, and although this is essentially a chronic disease, the onset is generally acute and there may be acute exacerbations. The acute onset, or any one of the acute exacerbations may progress to a typical pyelitis—a point which I would stress. When a case of acute urethro-trigonitis is seen immediately it develops, it is impossible to estimate whether it will become a pyelitis or not, since the symptoms of both conditions in the first twenty-four to forty-eight hours are identical in a majority of cases. 54% of the women in the pyelitis group to be reviewed later, gave a history of a urethro-trigonitis preceding the onset of their pyelitis.

Acute urethro-trigonitis.—In the majority of women the initial onset of urethro-trigonitis is sudden; they are seized with urethral pain and an urgent desire to micturate. The actual passage of urine is extremely painful and even when the bladder is emptied

Dr. R. J. Ludford raised the question whether the sensitivity of leukaemia cells was related to the frequency of mitosis. Professor A. P. Dustin had often drawn attention to the fact that the lymphoid tissues were specially sensitive to his "poisons caryoclastiques", which included a variety of chemical compounds and ionizing radiations. Then Lits, Kirschbaum and Strong reported that a rapidly growing lymphoid mouse tumour with which they worked was extremely sensitive to the mitotic poison, colchicine. Some tumours appeared to regress completely after treatment but always recurred so that the mice died ultimately of leukaemia. While it is generally true that the more rapid the growth of cells, the more readily they are injured by toxic substances, nevertheless cells of different tissues exhibit different susceptibility to poisons. There is the possibility that the relatively small mass of cytoplasm in proportion to nuclear volume renders cells of the lymphocyte type particularly sensitive to injury by physical and chemical agents.

Professor G. R. Cameron asked Professor Engelbreth-Holm whether he had any explanation for the numerous hæmorrhages which so commonly accompany the more acute forms of leukaemia. He had frequently examined such hæmorrhages by means of serial sections and was unable to come to any conclusion as to their nature. Rupture of vessels could not be established. Capillaries were most frequently a site of bleeding, and it was difficult to associate any structural change in them with the extravasations of blood.

He also inquired whether Professor Engelbreth-Holm had any information about the action of nitrogen mustards in leukaemia. Some of these compounds were water soluble, and could be made suitable for administration; in fact, some work had already been done in America. The nitrogen mustards, like the classical sulphur-containing mustard gas, have a specific destructive action on the granulocyte-forming tissue of the bone-marrow, as well as on the lymphoid tissue. It was possible to lower the white cell content of the blood by means of small doses without any grave disturbance of other tissues. The effects were temporary, however, and there was no evidence of maintained improvement. A great deal more research work needed to be done on this subject and it might be possible by means of co-operation between the chemist and the clinician, to obtain a potent compound which was safe and exerted the minimal harmful effects.

Dr. L. Foulds agreed with previous speakers about the difficulties in the diagnosis and classification of the leukoses and referred to transitional forms between typical leukoses and typical neoplasms in fowls.

Professor Engelbreth-Holm in reply to Dr. J. M. Alston: The problem of how aleukæmic leukaemia is to be understood is rather obscure. I do not think that it is necessary to assume a double failure of function. We have to wait for further information whether the suggestion of Rohr is right. Rohr is of the opinion that aleukæmic leukaemia occurs when the leukaemic processes are restricted to the bone-marrow, whereas the leukaemic picture will only develop in those cases where leukaemic processes are found outside the skeleton (spleen, liver, &c.). I am not convinced myself that this suggestion is correct, but Dr. C. Johansen in Copenhagen, in an exclusive work not yet published, thinks that Rohr is right.

As to the aetiology of leukaemia the view of Gohs was put forward by Dr. Rothe Meyer and myself in 1933. "The lytic substance" is obviously nothing but the virus in fowl leukaemia and this hypothesis only concerns fowl leukaemia and Rous sarcoma.

In reply to Professor G. R. Cameron: The explanation for the hæmorrhages is, I should think, thrombopenia. The hæmorrhages are first of all seen in cases of stem-cell leukaemia and lymphogenous leukaemia, where thrombopenia is marked, whereas they are lacking in myelogenous leukaemia in which the number of thrombocytes is normal or even increased.

I have no experience of the action of nitrogen mustard.

3% of the group gave a history of a previous abortion, and most of these were eight to ten years before, although one woman stated that her symptoms began after a dilatation and curettage two years previously. Under 1% of the pyelitis cases had had an abortion within three months of their pyelitis. I would say that the case against abortion is non-proven.

In the same way, normal childbirth would not seem to be an important ætiological factor. As one would expect, the majority of women in this age-group are married, but although many women say they were perfectly well before they became pregnant, the percentage of childless women (53%) is extraordinarily high.

The next generalization was the surprisingly low incidence of accompanying pelvic pathology other than cervical erosion; this latter undoubtedly has a very close relationship to urethral inflammation. While agreeing that gross pelvic pathology must always be corrected in women suffering from urinary symptoms, it is important to remember that cystocele *per se* is not a common cause of such symptoms.

The physical examination of these patients may therefore reveal no abnormality at all and a catheter specimen of urine is next obtained; here, of course, lies another trap, since although the urine may contain red blood corpuscles, pus cells and *B. coli*, it is usually crystal clear, contains no deposits and may even be sterile on culture; this fact has caused many surgeons to lose interest in these cases since they argue that no inflammatory pathology can be present if the urine is clear and sterile. If these women are cystoscoped in the lithotomy position so that the vulva can be carefully inspected, it will be noted that in the more acute cases the urethral orifice is frequently oedematous and hyperæmic, but that in the long-standing cases there is no apparent pathological condition. Only three instances of caruncle occurred in this whole series. However, narrowing of the urethral lumen is one of the commonest findings and it should come as no surprise if a 22 Charrière cystoscope cannot be introduced into the bladder. Many authors have now commented on this phenomenon, especially Stevens and Winsbury-White who consider that a urethral lumen which will not admit a 26 French sound is contracted. Urethral dilatation may be necessary therefore before cystoscopy can be performed. The cystoscopic findings in these cases vary but in the great majority of them the bladder shows the normal pinky yellow colour, while the ureteric orifice and the trigone may be normal as well. Symptoms in these women lead one to make a diagnosis of cystitis which is disproved time and time again by cystoscopy, and I feel that in general a diagnosis of cystitis is made far too loosely; as a primary lesion it is a rare condition. A localized trigonitis, however, is commonly associated with this syndrome. At times it may only involve the front of the trigone near the urethral orifice or it may run up along the area of one of Mercier's bars towards the ureteric orifice. Again, it may be absent altogether, but one thing is definite, it is never present without a similar or worse degree of pathology in the urethra and this would indicate that the inflammation commences in the urethra and spreads back to the trigone in most cases.

In seeking a cause for these women's symptoms a rapid routine cystoscopy may, therefore, reveal no abnormality and it is not until the instrument is withdrawn to show the margin of the internal urethral orifice that signs of pathology are evident. A collar of large congested vessels may be seen but the surest sign of trouble is the presence of oedematous, translucent, pedunculated or sessile polypi. It may only be possible to see these structures by holding the cystoscope obliquely so that it makes an angle of nearly 45 degrees with the axis of the urethra. A foroblique telescope is much better for the purpose but, of course, the urethroscope is the ideal instrument. These polypi appear singly or in clusters, usually between 10 and 2 o'clock, some are solid, rigid hillocks (an excellent term used by Winsbury-White, 1939), others are pedunculated and translucent and may burst when the beak of the instrument is pressed on them, and certainly if touched with the diathermy current.

Much research has been done on these polypi or hyperplastic changes as they have been termed (Hyams, 1944). Some workers think they are glands analogous to the male structure while others deny that there are glands in the female urethra, but all agree that they are pathological. I have removed several of the larger polypi with the cold punch, but the sections merely show evidence of chronic inflammation in a fibrous tissue matrix. No gland tissue has been seen.

Symptoms in relation to clinical findings.—These hyperplastic urethral changes are found so often in association with the symptoms of frequency and dysuria, &c. that there can be little doubt they are a part of the syndrome. However, although the clinical

the desire persists, and patients have reported how they were forced to sit on the lavatory for hours on end passing only a few drops of urine at a time. Terminal hæmaturia is common at this stage. Sometimes dysuria is present without any frequency at all, particularly in young women who say that they can hold their urine for four to five hours with comfort, but are afraid to micturate. Under such conditions acute retention may easily develop.

The acute symptoms which are associated with very marked constitutional effects, may last for several days, perhaps being severe enough to confine the patient to bed, but more usually the whole picture is less severe and the symptoms have completely subsided in a week or so. Mostly these acute cases are seen and treated by the general practitioner as "cystitis" and if they subside rapidly they never reach the out-patient department.

During the acute stage the urine may be infected with *B. coli* and contain pus and red cells, but it is surprising how quickly it will clear completely in some cases while the symptoms will remain. Cystoscopy performed very shortly after the acute phase may reveal no abnormality in the bladder mucosa at all, but the trigone and urethra are nearly always inflamed. The urethroscopic findings are, however, very transient and there may be nothing abnormal to see after a week or so. It is not until a chronic state develops that gross findings become common.

Chronic urethro-trigonitis.—A high proportion of cases settle down into a state of chronic urethral irritability, which, punctuated by acute exacerbations, may go on for months or years before the surgeon sees them, unless they develop an attack of pyelitis. The symptoms in these women are primarily frequency and dysuria, the frequency often being worse in the morning than later in the day, and although nocturia is common, it is never as severe as in tuberculous cases and may be absent altogether. Dysuria of a burning nature usually precedes or follows, though it may accompany the act. Sometimes dysuria is present without any frequency at all, particularly in young women, where pain or discomfort long after micturation may be the sole symptom. On the other hand the dysuria is often associated with urgency or precipitancy which may be so acute as to produce actual incontinence. A feeling of incomplete emptying of the bladder, suprapubic pressure and attacks of terminal hæmaturia are common findings.

Folsom (1934) and Winsbury-White (1933*a*) have both drawn attention to referred pain from the female urethra, such as pain in the loin, groin, thigh or suprapubic region. Folsom describes the special iliac type where multiple abdominal operations have usually been performed without relief. We must all have seen such cases. Personally I believe that many of these pains are due to an associated ureteritis. It is a surprising fact that women will put up with such symptoms for years on end before seeking advice.

The clinical data for this paper has been derived from a study of 433 women of the child-bearing age (15 to 47 years), who complained of some, or most, of the urethral symptoms already referred to, or who were admitted with pyelitis. Apart from a general systemic and a careful gynecological examination, a full urological investigation was made in every case; this latter included microscopy and generally culture of the urine, cystoscopy and urethroscopy and in many cases excretion pyelography. It must be emphasized at this stage that it may be impossible to demonstrate the true urethral pathology by cystoscopy alone and the urethroscope, preferably an irrigating instrument such as the Geiringer or Swift Joly is essential.

The total number of patients with evidence of urethritis was 310, 132 having an associated pyelitis as well. A noticeable feature was that more than half of them had suffered their symptoms for a year or more while most of them had received medicinal treatment from their private doctors with varying degrees of relief, but the symptoms had quickly returned. The histories in some cases went back eight to ten years, exacerbations being treated with alkalies, &c.

The age distribution is, I think, important. 72% (35+37) of the 187 urethro-trigonitis cases were evenly distributed between the 21-30 and 31-40 age-groups. However, a detailed analysis of these women showed that the first onset of urethral symptoms dated back to the 21-30 age-groups in 48%, so that the chronic cases tend to be seen in the 31-40 age-group.

63% of the pyelitis cases occurred in the 21-30 age-group, at an age in fact when acute urethro-trigonitis is commonest.

Incomplete abortion has always been given as a frequent cause of urinary infection, but its role as an ætiological factor in urethro-trigonitis is not very convincing. Only

3% of the group gave a history of a previous abortion, and most of these were eight to ten years before, although one woman stated that her symptoms began after a dilatation and curettage two years previously. Under 1% of the pyelitis cases had had an abortion within three months of their pyelitis. I would say that the case against abortion is non-proven.

In the same way, normal childbirth would not seem to be an important ætiological factor. As one would expect, the majority of women in this age-group are married, but although many women say they were perfectly well before they became pregnant, the percentage of childless women (53%) is extraordinarily high.

Symptoms in relation to clinical findings.—These hyperplastic urethral changes are found so often in association with the symptoms of frequency and dysuria, &c. that there can be little doubt they are a part of the syndrome. However, although the clinical

evidence and the papers of many workers support this assumption, I have heard it argued that since these urethral findings are so common they can be of no significance. It is obviously a very important point and it was therefore decided to examine the urethra of a control series of women of the same age-group who had never at any time complained of any symptoms of abnormal micturition. The selection was rigid in that micturition by day must not be oftener than three-hourly, no nocturia, dysuria, scalding urgency or stress incontinence was allowable, and there had to be no previous attack of cystitis or pyelitis during childhood or pregnancy, or particularly following marriage. The results of this investigation are interesting. Before a series of 70 women with abnormal symptoms could be collected, over 200 women had to be questioned closely, i.e. 2 in every 3 women gave a history of some previous disturbance of micturition. In the average parous woman, nocturia would appear to be the rule, while urgency and day frequency at hourly intervals are not unusual. This shows the high incidence of minor degrees of urogenital pathology and is surely a reflection on our profession for taking so little interest in it. The 70 symptomless, normal women were admitted to hospital for various conditions such as interval appendicectomy, herniotomy, incomplete abortions, minor orthopaedic lesions, &c., and they were all urethroscopied under general anaesthesia; the urines in every case were normal. A further 19 random controls were selected for urethroscopy who, although they were not suffering from any urinary symptoms at the time, did give a history of previous attacks of cysto-urethritis.

A common error in medical papers is to present a small series of cases, admit that it is small, too small to enable any conclusions to be drawn, and then straightaway proceed to draw these conclusions. I am therefore presenting these figures with comment for whatever they are worth.

Urethral polypi and hillocks were present in 5 of the 70 controls, but all of these women were cases of abortitious or salpingitis. Nothing pathological was found in women suffering from non-genital lesions. Of the 19 women symptomless at the time but having a previous urinary history, 13 or 68% showed evidence of urethral pathology. 70% of these 89 women were married and the only single woman to show any urethral changes was recovering from a salpingitis.

These figures do at least suggest that urethral polypi and hillocks are rare in previously uninfected urethra, and that when present they do probably indicate an inflammatory condition.

Mode of infection.—A careful history is most instructive and revealing in these women. The first symptoms date from the time of marriage in so many cases that there can be no doubt whatever that the sexual organs are very closely bound up with the aetiology of the condition. The first onset of urethral symptoms developed within three months of marriage in 80% of the women in the series. In 10% symptoms developed immediately after marriage and were duly recognized as so-called "honeymoon" cystitis. On the other hand, it is not only defecation which precipitates the attack; coitus after a prolonged interval appears equally to blame and numerous women who have been married for years and even borne children, complained of their first attack during their husband's leave from the Services.

Lymphatic spread of infection from the cervix and external genitalia to the trigonum undoubtedly occurs and the close relationship between erosion of the cervix and urethro-trigonitis is now generally accepted. Experimental work by Winsbury-Whitcomb and others supports this assumption, whilst clinically one finds it a waste of time to try and treat the chronic urethritis without, at the same time, attending to a cervical erosion, if present.

On the other hand, I believe that in the majority of cases the primary acute infection reaches the urethra as a direct ascending infection from the vulva. Whichever view is correct, the vulva and external genitalia are still the source of infection and I see no reason for blaming septic foci in nasal sinuses, gall-bladders, and other distant organs. The external urinary meatus is bathed in bacteria all day long, mostly non-pathogenic but contaminated with colon bacilli and other organisms after each act of defecation. Normally the healthy urethra is able to resist infection but unusual trauma such as prolonged unaccustomed cycling or defecation or coitus after a long interval, providing the minute abrasions and congestive state necessary for the organisms to gain entry to the tissues. As previously stated, the acute stage is not often seen in hospital but when it is, colon bacilli, streptococci or staphylococci can usually be cultured from the urethral smears. This is in contrast with the chronic form of this disease where urethral smears are either sterile or merely show diplococci, very occasionally staphylococci.

lococci, but hardly ever colon bacilli. Pus cells, however, are present if micturition has not occurred for several hours.

Six women with honeymoon urethro-trigonitis were encountered in the acute stage, but will be discussed later with the pyelitis cases.

Pyelonephritis.—I now wish to discuss the aetiology of pyelonephritis in women of this same age-group. The bulk of the literature on this subject is concerned with the possible route by which infection reaches the kidneys. The popular theory is that of hæmatogenous infection from some distant focus, that is, a bacteraemia. The second theory is that of ascending infection either up the lumen of the ureter, probably very rare, or via the peri-ureteric areolar tissue or the lymphatics. Final proof is still a long way off. The hæmatogenous theory supposes that organisms from the gall-bladder, appendix, colon, or hæmorrhoids, &c., somehow gain entry to the blood-stream setting up a bacteraemia which in turn causes a pyelonephritis. Obviously, this sequence of events can occur, but it seems most unlikely that it is the usual mode of kidney infection. There is no proof that a bacteraemia is present before the onset of a pyelitis, although admittedly, positive blood cultures have been recorded during the height of a rigor in pyelitis, but this does not prove that the infection is brought by the blood-stream to the kidney. In none of my cases was a rigor the presenting symptom, in fact the rigors, which were common before the use of sulph drugs, generally occurred at the height of the infection, often only after several days, and this is surely more in favour of a theory that the rigor is due to a liberation of organisms from the kidney into the blood-stream and not vice versa.

Even assuming that a coliform or other bacteraemia does occur on occasion and remain symptomless—and this is non-proven—it must next be decided whether this bacteraemia can produce a clinical and pathological picture similar to the usual clinical pyelitis. Experimental pyelonephritis has been produced by many workers, notably Mallory (1940), and his colleagues, who injected saline emulsions of *B. coli communis* intravenously to rabbits. It was found that if the ureter had been previously obstructed, pyelonephritis developed in this kidney but not in its fellow. These results were obtained in 75% of their experiments. If the ureter was not interfered with no pyelonephritis developed in any of their animals. Lucas (1908) explained these results following ureteric obstruction by demonstrating a slowing of the venous circulation as a result of the raised intra-ureteric pressure, and he thought this allowed more time for the circulating organisms to gain a foothold. Although this theory could be used to explain the mode of infection in congenital hydronephroses, &c., it seems rather strong evidence against a hæmatogenous infection in an anatomically normal kidney. It might even be thought to explain the mode of infection in pyelitis of pregnancy were it not for the fact that we now know there is a greatly increased blood supply to the kidney during pregnancy; also, of course, the intra-ureteric pressure in pregnancy is less, not greater than normal (Traut, 1936). The supporters of the hæmatogenous theory believe that the coliform organisms come from the bowel, and I have heard it said, and it is stated in many textbooks, that some acute gastro-intestinal upset frequently precedes the onset of a pyelitis; this is not true. Admittedly, one case in the 246 suffered from diarrhoea lasting three days before her pyelitis, but in general the incidence of associated chronic gastro-intestinal disease was very low: 2 cases of mild cholecystitis, 2 probable peptic ulcers and a case of colitis: statistically insignificant in women of this age-group. Personally, I think that all the experimental evidence brought forward in favour of a blood-borne infection in pyelitis is most unconvincing, while much of it could be used as counter-evidence. The hæmatogenous infection seldom fits into the clinical picture whilst it is difficult to see how it can explain recurrent attacks of pyelitis.

The next theory is that of an ascending infection from the lower urinary tract—at one time the popular theory. Earlier workers assumed that the organisms travelled up the lumen of the ureter, but this is now thought to occur very rarely in the presence of a normal uretero-vesical orifice.

Ascending infection up the peri-ureteric areolar tissue remains for consideration; this is denied by many workers who assert that the lymphatics of the ureter run horizontally to the lumbar nodes and not vertically upwards; but some years ago Winsbury-White (1933b) demonstrated that Indian ink particles injected to the base of the bladder were eventually found in the hilum of the kidney. This work has not received the full recognition it deserves, especially in this country. Severe cases of urethro-trigonitis frequently have symptoms and signs of a peri-ureteritis and this I think is only a stage on the way to a clinical pyelitis.

evidence and the papers of many workers support this assumption, I have heard it argued that since these urethral findings are so common they can be of no significance. This is obviously a very important point and it was therefore decided to examine the urethra of a control series of women of the same age-group who had never at any time complained of any symptoms of abnormal micturition. The selection was rigid in that micturition by day must not be oftener than three-hourly, no nocturia, dysuria, scalding, urgency or stress incontinence was allowable, and there had to be no previous attacks of cystitis or pyelitis during childhood or pregnancy, or particularly following marriage. The results of this investigation are interesting. Before a series of 70 women with no abnormal symptoms could be collected, over 200 women had to be questioned closely; i.e. 2 in every 3 women gave a history of some previous disturbance of micturition. In the average parous woman, nocturia would appear to be the rule, while urgency and day frequency at hourly intervals are not unusual. This shows the high incidence of minor degrees of urogenital pathology and is surely a reflection on our profession for taking so little interest in it. The 70 symptomless, normal women were admitted to hospital for various conditions such as interval appendicectomy, herniotomy, incomplete abortions, minor orthopaedic lesions, &c., and they were all urethroscopied under general anaesthesia; the urines in every case were normal. A further 19 random controls were selected for urethroscopy who, although they were not suffering from any urinary symptoms at the time, did give a history of previous attacks of cysto-urethritis.

A common error in medical papers is to present a small series of cases, admit that it is small, too small to enable any conclusions to be drawn, and then straightway proceed to draw these conclusions. I am therefore presenting these figures without comment for whatever they are worth.

Urethral polypi and hillocks were present in 5 of the 70 controls, but all of these 5 women were cases of abortions or salpingitis. Nothing pathological was found in 42 women suffering from non-genital lesions. Of the 19 women symptomless at the time, but having a previous urinary history, 13 or 68% showed evidence of urethral pathology. 70% of these 89 women were married and the only single woman to show any urethral changes was recovering from a salpingitis.

These figures do at least suggest that urethral polypi and hillocks are rare in a previously uninfected urethra, and that when present they do probably indicate an inflammatory condition.

Mode of infection.—A careful history is most instructive and revealing in these women. The first symptoms date from the time of marriage in so many cases that there can be no doubt whatever that the sexual organs are very closely bound up with the aetiology of the condition. The first onset of urethral symptoms developed within three months of marriage in 80% of the women in the series. In 10% symptoms developed immediately after marriage and were duly recognized as so-called "honeymoon" cystitis. On the other hand, it is not only defloration which precipitates the attack: coitus after a prolonged interval appears equally to blame and numerous women who have been married for years and even borne children, complained of their first attack during their husband's leave from the Services.

Lymphatic spread of infection from the cervix and external genitalia to the trigone undoubtedly occurs and the close relationship between erosion of the cervix and urethro-trigonitis is now generally accepted. Experimental work by Winsbury-White and others supports this assumption, whilst clinically one finds it a waste of time to try and treat the chronic urethritis without, at the same time, attending to a cervical erosion, if present.

On the other hand, I believe that in the majority of cases the primary acute infection reaches the urethra as a direct ascending infection from the vulva. Whichever route is correct, the vulva and external genitalia are still the source of infection and I see no reason for blaming septic foci in nasal sinuses, gall-bladders, and other distant organs. The external urinary meatus is bathed in bacteria all day long, mostly non-pathogenic, but contaminated with colon bacilli and other organisms after each act of defecation. Normally the healthy urethra is able to resist infection but unusual trauma such as prolonged unaccustomed cycling or defloration or coitus after a long interval, provide the minute abrasions and congestive state necessary for the organisms to gain entry to the tissues. As previously stated, the acute stage is not often seen in hospital but, when it is, colon bacilli, streptococci or staphylococci can usually be cultured from the urethral smears. This is in contrast with the chronic form of this disease where urethral smears are either sterile or merely show diplococci, very occasionally staphy-

pyelitis occurring in a pregnant woman but owing to the associated physiological dilatation and stasis the symptoms are more severe and the treatment is more difficult.

Returning to the groups A and G on Table I, congenital anomalies and hydronephrosis, it is generally agreed that patients with congenital anomalies are more prone to urinary infection than normal individuals. One can readily understand that a few pathogenic organisms which would not affect a normal kidney might produce a serious infection in a congenital lesion with stasis, but given this stasis the route by which infection reaches the kidney is still disputed. Mallory's experiments (1940) with obstructed ureters show that a hæmatogenous infection is certainly possible under such circumstances, but I do not feel that it is the usual route and I would like to describe some cases where an ascending infection was more than likely.

CASE I.—A woman of 22 was admitted following defloration, with an acute urethritis later becoming a typical pyelitis. The clinical picture resolved rapidly with chemotherapy, but the patient was seen again ten days later after her discharge from hospital, with a return of symptoms on resuming normal sexual relations. Her pyelogram revealed a congenital hydronephrosis, later proved to be due to an aberrant vessel. This is a very good example of a congenital lesion with quite obvious stasis remaining perfectly symptomless for 22 years until it becomes infected from a urethritis.

CASE II.—A girl of 22 set off with a companion to cycle to Oxford. She was an inexperienced cyclist and having reached High Wycombe she became so "saddle-sore" she abandoned the effort and returned home by train. On the train she had scalding micturition with some terminal hæmaturia. Her urethritis persisted for five days when she was sent to hospital as a typical acute appendicitis because of tenderness in the right iliac fossa. The real cause of her trouble was infection in a bilateral megalo-ureter. She had repeated attacks of pyelitis after this one and finally died from uræmia.

There is little doubt that infection came from below in both of these cases.

There were 14 cases of honeymoon pyelitis which will now be considered in conjunction with the six cases of honeymoon urethritis already referred to, since they provide a very important ætiological link between urethro-trigonitis and pyelitis. Defloration urethritis is a very common condition, but it is usually mild and transient so that medical aid is seldom sought. It is hardly mentioned in the textbooks. Defloration pyelitis, however, is a well-recognized entity in the textbooks, most of which avoid any mention of the route by which infection gains access to the kidney. In all of these 20 women a careful history showed that following the attempt or the act of coitus, dysuria and frequency were experienced within a few hours, but it was several days before the unfortunate ones developed their pyelitis. Undoubtedly the primary infection was in the urethra in every case.

CASE III.—A 21-year-old girl was admitted from a Service hospital with a subsiding pyelitis. Three months previously she had been married during a forty-eight hour leave, and had developed a severe acute urethritis with terminal hæmaturia which lasted for five days. Usual tests for gonorrhoea were negative and a week later she went on a fourteen days' honeymoon which resulted in a further attack of urethritis, followed at the end of the week by a severe left pyelitis necessitating her admission to a hospital with rigors, &c. After this she had persistent frequency and dysuria with exacerbations following coitus until finally she developed a bilateral pyelitis during which I saw her. Her excretion pyelogram showed a congenital right dilated upper calix and a left small but otherwise normal-looking pelvis. Inspection revealed a very markedly contracted and oedematous urethra rendering instrumentation impossible without preliminary dilatation under an anæsthetic. Urethroscopy later showed a typical urethro-trigonitis but no polypi. Cystoscopy, however, revealed two complete left ureters, not showing in the excretion pyelogram. She also had a small cervical erosion. Here is a girl with congenital renal anomalies which remained symptomless for 21 years until she developed the urethritis. There can be little doubt that her pyelitis was an ascending infection.

An interesting postscript to this case was the fact that after her urine had been rendered sterile for three weeks, and her erosion cured, her next act of coitus brought on an acute urethritis lasting for forty-eight hours. She was therefore given sulphathiazole tablets with instructions to take 4 grammes during the twenty-four hours preceding coitus; this regime proved completely effective.

CASE IV.—This illustrates the point that "honeymoon" pyelitis is not confined to brides. A 33 year-old woman with one child aged 3 was admitted to hospital with a mild pyelitis and a history of frequency and dysuria for some months.

Examination only revealed a chronic urethritis with polypi. She became symptomless after diathermy fulguration of these polypi. However, she was readmitted twice more at five-week intervals and this made me suspicious. Close questioning revealed that her husband came on Service leave every five weeks and her attacks followed intercourse. Subsequent attacks of pyelitis and/or dysuria were prevented by her taking sulphathiazole twenty-four hours before her husband's return. Subsequent treatment of his and her non-specific urethritis has resulted in a cure for both partners but the wife still insists on her prophylactic sulphathiazole.

Returning to Table I again, Group J shows that 58.5% of the pyelitis cases had urethroscopic evidence of the presence of urethro-trigonitis while Group K indicates that at least 54% of them had this urethro-trigonitis before the onset of their pyelitis,

Peri-ureteritis.—This is a well-recognized entity in America, but is seldom described in this country. The symptoms are a dull, almost continuous pain in one or both iliac fossae and groins, interspersed with mild spasms of colic. The symptoms are variously made worse or better by the onset of menstruation and this can be accounted for by the fact that the ovary and the lower end of the ureter have an almost common nerve and blood supply.

In the fairly large proportion of women who are still unrelieved of their symptoms by appendicectomy and attention to cystic ovaries, the passage of a ureteric catheter may produce a dramatic cure. In many cases the mere dilatation of the urethra alone will relieve the ureteric pain.

I believe that this peri-ureteritis is a definite clinical entity, closely related to urethro-trigonitis. One finds repeatedly that while ureteric catheterization is relatively painless in normal women, those suffering from urethro-trigonitis will complain of deep iliac fossa pain the moment the catheter is introduced.

If excretion pyelograms are performed during the active stages of an acute urethro-trigonitis, or during an exacerbation, very poor visualization of the upper urinary tract is obtained. This is due to pelvic and ureteric irritability producing rapid emptying as shown by the early concentration of dye in the bladder. This is only a transitory phenomenon and normal visualization returns when the urethral symptoms are relieved.

Although many radiologists will not agree, I believe that evidence of peri-ureteritis is frequently seen in excretion pyelograms particularly in cases of chronic urethro-trigonitis. Ureteric kinking if it is constant and cannot be corrected by alterations in breathing or posture, is pathological and is due to peri-ureteric adhesions.

The extreme kinking seen during pregnancy will return to normal so long as the patient does not develop a severe pyelitis. After a severe infection these kinks are definitely permanent. Similar, but obviously not such marked, permanent kinks are seen in urethro-trigonitis patients, who have never had an actual pyelitis, so that there is as much evidence in favour of an ascending peri-ureteritis from the trigone, as there is in favour of a descending one from the kidney.

Occasionally the ureters and pelves are seen filled all the way down, either due to a mild atonia or to a mild spasm at the lower end. This condition will generally return to normal when the urethral pathology is attended to.

Clinical data.—Table I shows the data of the 246 pyelitis cases under review and a detailed study leaves me convinced that a pyelitis very rarely develops in a patient with

TABLE I.—246 PYELONEPHRITIS CASES

		134 Non-pregnant	112 pregnant	Total
A	Congenital lesions	0%	6%	6.0%
B	Calculi	5.3%	5.3%	5.3%
C	Hydronephrosis	5.9%	4.4%	5.2%
D	Tuberculosis	1.5%	0.8%	1.2%
E	Gross U.G. pathology	18.7%	16.5%	18%
F	Previous U.G. infection	35.8%	35.6%	35.7%
G	Patients with previous infection and/or gross U.G. pathology	50.7%	52.6%	51.2%
H	Defloration	14 cases — 10.4%	—	10.4%
I	Clinical proof of urethro-trigonitis	62%	55%	58.5%
K	Symptoms of a urethritis preceding loin pain	61.7%	33.3%	54%

A combination of some gross pathology, or a urethrotrigonitis or a previous history of urinary tract infection was present in 81% of the 246 women.

a previously anatomically normal or uninfected renal tract. It will be seen that 18% of the non-pregnant and 16% of the pregnant women had some gross urological pathology which in many cases called for major surgical intervention. The next important finding was that 35% of the non-pregnant and 35% of the pregnant women gave a history of some previous urinary tract infection, such as, a previous attack of pyelitis, cystitis, or a urethritis, severe enough to make them seek medical advice. Many more women complained of attacks of frequency, dysuria, urgency, or perhaps even terminal hæmaturia which they called a chill on the bladder, but did not bother to see a doctor about it. This means that preceding the attack of pyelitis under consideration there was proof of some urinary tract pathology in 50% of the non-pregnant and 52% of the pregnant women.

The incidence of pyelitis of pregnancy is very little greater than the incidence of pyelitis in non-pregnant women of the same age-group. The aetiological factors appear to be the same and there is nothing special about pyelitis of pregnancy; it is merely a

pyelitis occurring in a pregnant woman but owing to the associated physiological dilatation and stasis the symptoms are more severe and the treatment is more difficult.

Returning to the groups A and C on Table I, congenital anomalies and hydronephrosis, it is generally agreed that patients with congenital anomalies are more prone to urinary infection than normal individuals. One can readily understand that a few pathogenic organisms which would not affect a normal kidney might produce a serious infection in a congenital lesion with stasis, but given this stasis the route by which infection reaches the kidney is still disputed. Mallory's experiments (1940) with obstructed ureters show that a hæmatogenous infection is certainly possible under such circumstances, but I do not feel that it is the usual route and I would like to describe some cases where an ascending infection was more than likely.

CASE I.—A woman of 22 was admitted following defloration, with an acute urethritis later becoming a typical pyelitis. The clinical picture resolved rapidly with chemotherapy, but the patient was seen again ten days later after her discharge from hospital, with a return of symptoms on resuming normal sexual relations. Her pyelogram revealed a congenital hydronephrosis, later proved to be due to an aberrant vessel. This is a very good example of a congenital lesion with quite obvious stasis remaining perfectly symptomless for 22 years until it becomes infected from a urethritis.

CASE II.—A girl of 22 set off with a companion to cycle to Oxford. She was an inexperienced cyclist and having reached High Wycombe she became so "saddle-sore" she abandoned the effort and returned home by train. On the train she had scalding micturition with some terminal hæmaturia. Her urethritis persisted for five days when she was sent to hospital as a typical acute appendicitis because of tenderness in the right iliac fossa. The real cause of her trouble was infection in a bilateral megaloureter. She had repeated attacks of pyelitis after this one and finally died from uræmia.

There is little doubt that infection came from below in both of these cases.

There were 14 cases of honeymoon pyelitis which will now be considered in conjunction with the six cases of honeymoon urethritis already referred to, since they provide a very important ætiological link between urethro-trigonitis and pyelitis. Defloration urethritis is a very common condition, but it is usually mild and transient so that medical aid is seldom sought. It is hardly mentioned in the textbooks. Defloration pyelitis, however, is a well-recognized entity in the textbooks, most of which avoid any mention of the route by which infection gains access to the kidney. However, she was readmitted twice more at five-week intervals and this made me suspicious. Close questioning revealed that her husband came on Service leave every five weeks and her attacks followed intercourse. Subsequent attacks of pyelitis and/or dysuria were prevented by her taking sulphathiazole twenty-four hours before her husband's return. Subsequent treatment of his and her non-specific urethritis has resulted in a cure for both partners but the wife still insists on her prophylactic sulphathiazole.

Returning to Table I again, Group J shows that 58.5% of the pyelitis cases had urethroscopic evidence of the presence of urethro-trigonitis while Group K indicates that at least 54% of them had this urethro-trigonitis before the onset of their pyelitis,

as judged by the fact that symptoms of urethritis preceded the pyelitis, often by several days.

Taking the whole series, a combination of some gross pathology, or urethro-trigonitis or a previous history of urinary tract infection was present in 81% of the 246 women.

I would suggest therefore that pyelitis is seldom a primary disease in itself but is merely a dramatic incident occurring during the course of a generalized urinary tract infection.

In conclusion I would say that the female urethra is a very common source of latent urinary tract infection, neglect of which leads much needless suffering.

As for the relationship of the urethra to pyelonephritis, although actual proof is lacking the theory of ascending infection has as much, if not more, clinical evidence in its favour than any other theory.

There appears little doubt that a great majority of pyelonephritis patients have an underlying pathological condition and for this reason I would make a plea for their being regarded as surgical, not medical, cases, since only by this means will they receive full urological investigation.

Mr. H. P. Winsbury-White: A valuable experimental study bearing on the relationship between urethral and renal infections has been carried out by Helmholz of the Mayo Clinic. He injected cultures of living organisms into the urethra and on killing the animals (rabbits) the organisms were identified in inflammatory lesions in the renal substance. A point of considerable practical interest arising from these experiments is that in several instances urine taken from the renal pelvis at the time the kidneys were removed failed to reveal the presence of organisms on careful laboratory investigation.

The phenomenon of renal infection which is not substantiated by urinary findings is well known to us all in certain cases of renal abscess, but the co-existence of the two states in mild degrees of renal infection is not so well known. This is largely because in these mild infections we are almost entirely dependent on animal experiment for confirmation of the presence of a renal lesion.

Helmholz's experiments, however, open up a line of inquiry we can profitably follow in early cases of kidney pain, for if we investigate the urethra in all such cases, and in some of them find a lesion, and the treatment of this alleviates the renal symptom, it is not an unreasonable conclusion that there is a renal change which owes its origin to the urethral lesion.

Let us take a commonplace example: A young woman has had intermittent pain in one loin on and off for several years. There is mild chronic frequency which with the renal pain tends to flare up from time to time. Neither the laboratory report on the urine, nor the intravenous urograms throw any light on the cause of the symptoms. The cystoscopic picture shows that the general bladder cavity is quite normal in appearance, and unless we examine the front of the trigone and the internal urinary meatus with great care, it may escape our notice that inflammation exists in one or both of these localities. The examination of such a case should not be terminated without urethroscopy. Commonly this procedure will show chronic inflammatory changes in the posterior urethra.

The whole area of inflammation just referred to is small but compact, it can be properly described as a urethrotrigonitis, or in some cases a urethro-cervico-trigonitis, because the internal urinary meatus is also involved.

The lymphatic connexion between this bladder-neck region and the kidneys is of course outside the bladder and ureters, and the healthy-looking vesical mucosa which is seen on cystoscopy is apt to distract one's attention from the probability that the urethro-trigonitis has anything to do with the renal symptoms, but the disappearance—if this occurs—of the renal pain as a result of the appropriate treatment of the urethro-trigonitis is proof enough of the interdependence of the two widely separated conditions.

Developmentally the posterior urethra arises as a protrusion from the bladder. The zone comprising the front of the trigone, the internal urinary meatus and the posterior urethra is indeed entitled to our earnest attention because it is also involved in the following well-known conditions: Median bar formation; fibrous constriction of the internal urinary meatus; and the various prostatic changes we know so well.

Is it likely that these commonplace states at the bladder-neck suddenly begin to develop without apparent reason; or are they preceded by gradually occurring and insidious changes in the region concerned? Such a question must lack a definite answer unless routine observations are made in young patients who develop disturbances of micturition.

I have always approached the examination of children and young adults with chronic frequency and other disturbances of micturition, with the feeling that one is probably dealing with the incipient stages of diseased states with which we are all familiar in adult life.

In looking back over one's own cases of urethro-trigonitis which have been associated with upper urinary tract symptoms, one can divide them into several categories according to the nature of the renal symptoms: (1) Intermittent aching in the loin; (2) chronic aching in the loin; (3) attacks of pyelitis; (4) chronic pyelonephritis. There is a background of frequency of micturition in all these cases.

The proof of the dependence of the upper urinary tract changes and symptoms on the lower urinary tract pathology lies in the improvement in the renal symptoms, which goes hand in hand with the improvement in the urethro-trigonitis as the latter is given the appropriate treatment.

I have found it quite usual to control the tendency to attacks of pyelitis, by treating an existing urethro-trigonitis. I could recite innumerable cases of other kinds where kidney symptoms have been controlled in the same way.

One particular group of cases should be mentioned, however, because it is apt to be very distressing. I refer to attacks of cystitis and pyelitis which follow quickly upon sexual intercourse. Such a train of events is dependent upon trauma to a granu-lomatous urethra, and the symptoms come on within forty-eight hours of intercourse. I recently had a patient who complained of five attacks of cystitis two of which were accompanied by pyelitis. She was quite definite that each attack followed within forty-eight hours of intercourse. Naturally both she and her husband were worried about these incidents. Urethroscopy showed several large polypi in the posterior urethra. After appropriate treatment of the urethra, the attacks ceased.

Organisms in the urine.—It has been of some interest to divide these cases with renal symptoms into categories in relation to the presence of organisms in the urine, and in an ascending order of severity: (1) No organisms at all; (2) organisms intermittently in the bladder urine; (3) organisms chronically in the bladder urine; (4) organisms intermittently in the kidney urine; (5) organisms chronically in the kidney urine.

Modern anatomists have demonstrated lymphatics between rectum, cervix and bladder-neck. We know how *B. coli* is attracted to a well-prepared soil.

The lymphoid collections in the submucous tissue of the posterior urethra and bladder-neck which have been demonstrated by different research workers seem to be the initial foci of infection in these parts.

TREATMENT

Treatment which I have carried out for many years on the urethral foci is by urethral dilatation, but fulguration of urethral polypi is essential in certain cases. I believe that the benefit from the urethral dilatation is by promoting drainage from foci of infection.

There are, however, so many different ways in which this treatment can be carried out that we may expect an equal variety of results. It is therefore very unsatisfactory to state that urethral dilatation is good or it is bad, without giving details as to how the treatment has been done.

There are three phases in the symptoms following urethral dilatation. Each one of these phases varies in different cases, according to the circumstances of the case, and the judgment shown by the operator.

(1) *The immediate reaction.*—Often the only symptom is dysuria, lasting a few hours; but cystitis may occur. This generally means that the dilatation has been carried too far. I believe that it takes about two weeks for all local signs of an instrumentation to pass, therefore I never give the second dilatation until three weeks have elapsed since the first one.

(2) *The period of improvement of the symptoms under treatment.*—This is extremely variable, it generally lasts for about three weeks after the first treatment, but it may last for only three days, or it may persist for many months. In some cases no improvement need be expected in renal symptoms. If no improvement results in bladder symptoms in spite of several treatments, the genital system should be searched carefully, to be sure that there is not some adjacent focus of infection which has been overlooked.

(3) *The tendency to relapse.*—The first sign of this is the signal for the treatment to be repeated.

Technique

There are many faults which can be committed in connexion with this treatment, and in the course of having treated many hundreds of women, I have been guilty of many of them. Perhaps the easiest mistake to make is to carry the dilatation too far at a particular treatment. The next common mistake is to give the treatment too often.

Instruments

In women straight metal sounds graduated in the Charrière scale are the best. On the occasion of the first visit the calibre of the urethra should be gauged by taking a 24 Ch. instrument. On this occasion further dilatation should proceed only until an instrument is gently gripped. Subsequent dilations should proceed so as to increase one Charrière at each visit. For most women a maximum of 30 Charrière should be regarded as the top size, but many should never reach this; in odd cases 32 Charrière is the correct maximum size. One can only condemn the use of Hagar's cervical dilators; they are too crudely graduated for this purpose.

Intervals between the dilations.—For adults these should as a rule be gradually extended, although it may be necessary to vary these at certain points, according to progress. The intervals I generally allow after the first interval of three weeks are expressed in months as follows: 1, 1½, 2, 3, 4, 6, 9, 12, but it is important to be ready to extend an interval between treatment, when there is no tendency for symptoms to return.

It should be hardly necessary to add that badly conducted instrumentation will do more harm than good.

Mr. Clifford Morson drew attention to the experiments of Mottram on the effect of irradiation of the large bowel in which he showed that, when the mucin-forming cells of the mucous membrane were damaged, the colon bacilli migrated from its surface to the pericolic lymphatics and thence to the blood-stream. One could therefore postulate that a long-standing chronic constipation or other chronic lesion of the large gut which interfered with the function of the goblet cell would cause an infection of the urinary tract with the *Bacillus coli*. The bowel cannot be ruled out entirely as a source of infection. There were unquestionable cases of colon bacilluria in the female associated with lesions of the bowel such as diverticulitis and chronic constipation.

Mr. J. Gabe: I have had numerous opportunities of observing the urethroscopic and cystoscopic appearances described by Mr. Hanley and can testify to the favourable response of patients to appropriate measures, e.g. urethral dilatation, fulguration of polypi and cauterization of cervix. I noticed that neither Mr. Hanley nor Mr. Winsbury-White mentioned the frequent finding of residual urine in these cases.

I have often met with chronic urethrotigonitis in cases of pyelitis of pregnancy. To quote merely one example. A young woman had an attack of "cystitis" four months after marriage. Shortly after this she became pregnant. In the puerperium she had an attack of left-sided pyelitis but pain persisted in the left loin after the acute attack had subsided. Examination revealed the coexistence of a large cervical erosion, urethrotigonitis and a large left-sided hydronephrosis. Within a few months she again became pregnant and the left kidney was removed to prevent further trouble. The concomitant lesions are in the process of being treated.

One has heard it said that abnormal appearances such as have been so well and so fully described by Mr. Hanley are due to instrumental trauma, but having seen many normal urethrae one knows this is not true.

I might add that when I first became interested in this subject as the result of seeing Mr. Winsbury-White's work at St. Paul's Hospital I felt rather sceptical, but I must confess myself completely in agreement with the findings and with the efficacy of the established methods of treatment.

The following Cases and Specimens were shown:

Kidney

- (1) Crossed Renal Ectopia with Cystine Calculus in the Ectopic Kidney (Radiographs);
- (2) Calcium Infarction of the Kidneys (Radiographs).—Mr. J. D. FERCUSSON.

- (1) Partial Nephrectomy for Caliceal Calculi; (2) Completely Calcified Kidney (Radiographs).—Mr. J. GABE.

Solitary Cyst Simulating Splenomegaly.—Mr. HOWARD HANLEY.

Late result of von Lichtenberg's Operation.—Mr. MAURICE LEE.

Congenital Bladder Neck Obstruction with Crossed Renal Ectopia.—Mr. H. K. VERNON.

Ureter

Kidney and Radiographs of Gunshot Wound of Ureter.—Mr. A. W. BADENOCII.

Denervation of the Ureter for Persistent Pain (Patient was Demonstrated).—Mr. H. G. HANLEY.

Massive Ureteric Calculi.—Mr. H. K. VERNON.

Bladder

Leiomyosarcoma of Urinary Bladder.—Mr. J. GABE.

Cysto-Prostatectomy for Enlarged Villous Growth of Bladder.—Mr. MAURICE LEE.

External Genitals

Congenital Venous Angioma of Scrotum in a Boy of 4 Years. For Confirmation of Diagnosis and Opinion Re Treatment.—Mr. E. W. AINSWORTH-DAVIS.

(1) Seminoma; (2) Hæmatocele of Epididymal Cyst.—Mr. E. W. RICHES.

Urological Reflections

By SIR HENRY WADE, C.M.G., F.R.C.S.Ed.

AFTER some introductory remarks on the methods of urological diagnosis in vogue when he was a student, Sir Henry Wade continued:

Determination of renal function.—The determination of renal function by the physician is most commonly made by carrying out a urea concentration test or a similar method. In my experience the simpler method of blood examination, wherein the blood urea is estimated, the urea nitrogen or non-protein nitrogen and creatinine determined, has proved a most valuable diagnostic aid. There is, however, one method that I would put first of all, which many of the younger urologists are liable to overlook, and that is, the examination of the patient's tongue.

The Operative Treatment of Prostatic Disease: The prostatic gamble.—Castration: The first form of treatment I saw carried out for the relief of prostatic obstruction due to simple prostatic hypertrophy was by castration, a barbarous procedure, but one based upon an idea which has in it a certain germ of great truth.

Vasectomy: As the unfortunate patients occasionally suffered from a complete mental upset following this treatment it was modified to that of vasectomy, which also did no good but fortunately did no appreciable harm.

I left my post as a young Resident in the Royal Infirmary of Edinburgh to proceed to South Africa in the capacity of a civil surgeon, an individual who was described as one who received the pay of a Major, the rank of a Captain and the dress of a Hindu dispenser, and there was attached to the No. 1 General Hospital at Wynberg where my colleagues were Sir Charles Gordon-Watson, Frank Gairdner and certain others. After a stay of three weeks we were sent up country and for a year and ten months I never slept under a roof and lived on the open veldt and ultimately returned to teach Anatomy under Sir William Turner in the dissecting room of Edinburgh University during the winter, a contrast in existence that it took all my will power to survive. Following this came my further training in surgery as Resident and Clinical Tutor and Private Assistant, and I had the good luck to be appointed Conservator of the Royal College of Surgeons' Museum. I now decided on a course that at the time was thought to be unusual if not dangerous, to give up the practice of surgery entirely and become a whole-time Pathologist to the Royal Infirmary, Edinburgh, for two years. All the post-mortem examinations done on surgical cases were carried out by myself, and in certain of these the operation of prostatectomy had been carried out and I was interested to observe how frequently there was revealed a pronounced degree of hydronephrosis and how sometimes the renal secreting tissue was reduced to a thin membrane covering bags of water.

Visit to St. Peter's Hospital.—These were the days when Freyer was at the height of his well-deserved fame, and I came South to see him operate at St. Peter's and I well remember a case he dealt with. In company with a few others I sat on a bench in the operating theatre: facing us was the operating table and beyond it the wash-hand basin opposite which a clean roller towel hung up. The operation was carried out speedily and simply by that most dexterous surgeon, who removed the gland in one piece, introduced his drainage tube and enfolded the skin around it by suture and brought the specimen over to where we were sitting and demonstrated to us to his satisfaction the fact that he had removed the entire gland. Now at this stage a controversy existed as to whether his statement was in truth correct. Thomson Walker supported his view, and in common with others I studied the question.

The method I employed was first of all to make whole sections of 50 specimens that had been recently presented to the College Museum as illustrating simple prostatic hypertrophy. An interesting result followed this study where I found that 10% of these, unknown to the operator, were the site of a certain variety of carcinoma, which as we now know develops not infrequently from the simple enlargement. I also had whole sections made of the prostatic beds obtained at the post-mortem examination and these showed that the condition of simple hypertrophy was a hyperplasia limited in its extent which formed a rind or false capsule from the compressed and condensed uninvolved prostatic tissue, from beneath which the area of hypertrophy was enucleated most frequently in a single mass. Freyer, who had done so very much for humanity, was unconvinced. This would have mattered little if the consequences had not been serious, for, if simple hypertrophy is present and the rind or false capsule is formed the circumstances are ideal for the treatment of the case by suprapubic enucleation; on the other hand prostatitis may arise from other causes especially fibrosis or interstitial prostatitis and prostatic carcinoma; in neither of these is a false capsule formed and an attempt at enucleation from above may be fraught with serious consequences where the line of cleavage is extra-capsular involving the prostatic veins and lymphatics and the cellular tissue planes of the pelvis.

At this period the mortality that attended the operative treatment for prostatectomy was extremely high—in one Institution with which I was associated for ten years down to 1913 it amounted to 25% and on returning again to duty after being absent for five years' service in 1920 it still stood at 25% and during the year 1916 it had amounted to 40%.

Hugh Hampton Young.—The results of the work I carried out were shown by me at the International Medical Congress held in London in 1913, and there I first met Hugh Hampton Young of Baltimore and John Cunningham of Boston. The former was keenly interested in my exhibit which he published in the *Annals of Surgery* with unlimited illustrations in black and white and in colour. I was also invited to attend the following year at Johns Hopkins Hospital when the Buchanan Brady Institution founded by Diamond Jim Brady was to be opened as a Urological Department. The advent of war prevented this, but in 1920 the invitation was again extended and for several months I was in America and most of the time with Young in Baltimore. I arrived on a Sunday as his senior assistant was trying to get through to Atlantic City to ask his Chief's advice as regards a case that he had operated on in which he had used his punch to remove the bladder neck for interstitial prostatitis. By those who have been his assistants the value of this method was fully appreciated, but the handicap of the associated hæmorrhage was also realized so that his assistant Caulk, who was now in St. Louis, modified the punch by using a diathermy knife to divide the bladder neck, and another of his colleagues, Gerratty, introduced the sphincterotome which cuts through the bladder neck.

The practice of transurethral prostatectomy now swept through the United States and many modifications of the original method were introduced. Most of these were modified forms of the diathermy knife. Bumpus in the Mayo Clinic at Rochester applied the diathermy current to the gland to be removed before it was cut, but this was modified later by Thomson who used what really was, in principle, the original Young's punch and subsequently arrested the bleeding by diathermy.

Perineal prostatectomy: Like certain others I at this time took unkindly to a prostatic gamble. I was drawn to the technique of perineal prostatectomy practised by Hugh Young, a procedure he adopted in all his cases of simple enlargement. To carry it out required a special technique with special instruments, a very accurate anatomical knowledge and well-trained team. As one who practised general surgery, the lessons I learned when doing this operation improved my operating technique in certain other cases.

Malignant disease.—It was essentially similar to that adopted in the operation of total excision of the prostate by the perineal route for malignant disease. A knowledge of it enabled the treatment of malignant disease of the prostate by interstitial radiation to be properly carried out. It also improved my technique in the operative treatment of carcinoma of the rectum by excision, particularly where simple prostatic enlargement was combined with carcinoma of the rectum, a not-infrequent combination.

Total excision of the genital tract for tuberculous disease.—A technique very similar was employed by Young in his operation of total excision of the genital tract for tuberculous disease. The epididymis, vas deferens, seminal vesicles and frequently a part of the prostate were removed in one piece, the exposure being similar to that for

perineal prostatectomy. The urethra, however, was not opened and the prostate and vesicles were brought down by Young's seminal vesical tractor. In my opinion this operation necessitates the most delicate and most skilful operative dexterity in the practice of urology.

Congenital vesical sphincteric stenosis (prostatic valve).—When I was Conservator of the Royal College of Surgeons' Museum, it was my custom every Tuesday at two in the afternoon to lecture to senior students and graduates on various aspects of surgical pathology, and when dealing with cases of neuromuscular inco-ordination or achalasia, I used to demonstrate specimens of what John Thomson, the father of all paediatric physicians, called congenital vesical sphincteric stenosis, a condition found sometimes in the stillborn, met with in infants and not uncommonly seen in later life, and one which, by the backward pressure it exercises, may prove fatal by the damage it causes to renal functional activity. As far as I am aware Hugh Young was the first to treat this condition by operation. In 1920 I saw him operate on one of his first cases, a youth called Bobby. The bladder had previously been opened and on viewing its interior, the widely-opened internal sphincter and the dilated prostatic urethra could be inspected. Young employed a specially made tiny punch to remove what he described as the prostatic valve causing the obstruction. In all his subsequent cases Young described the condition as one of congenital prostatic valve.

Stricture of the ureter.—During this visit I was introduced by Guy Hunner to a new disease, which he described as stricture of the ureter, and saw him carry out the treatment which he did by making a bulbous end of wax on the tip of a ureteral catheter and 15 cm. from the tip he made a spindle of molten wax as a dilator. A Kelly cystoscope combined with the air inflation with the patient in the genu-pectoral position was employed. Despite the charm of the surgeon I did not fall for his operation, but that is another story.

The treatment of bladder tumours by diathermy.—When Beer of New York was a student at Vienna he saw Nitze removing bladder tumours by trans-urethral snares. He suggested the employment of diathermy but received no encouragement. On his return to New York, however, he conducted his research and Wappler Brothers made for him the necessary instruments and thus was introduced a line of treatment which has revolutionized the practice of urology in one direction and proved of great benefit in cases of villous papilloma of the bladder and certain other conditions.

The role of surgery in renal tuberculosis.—It has been my lot to excise many kidneys, the site of tuberculous disease. At the same time, in almost all cases, this has been accompanied by an explanation and an apology to my audience and a hope for a better treatment in the future. The explanation of my conduct is that as a student and House Surgeon there was hardly an operating day passed but in several of the seven operating theatres of my hospital joints were excised or bones resected for tuberculous disease. This treatment is now unknown, for at the same time there was in Liverpool Thomas and his nephew, Robert Jones, showing how a better result could be obtained, without mutilation, by conservative means. Their influence gradually prevailed, so that such operations as I have mentioned are now unknown. If such be the case, why is a similar result not possible in renal surgery? Why cannot a cure by conservative measures be also accomplished here? The underlying process of natural healing is identical in both cases. The explanation, of course, is in the environment of the disease. In both the infection is combated and walled off and the debris conveyed to a free surface and there discharged and the sinus healed. Unfortunately the free surface in the kidney is the renal pelvis and into it the debris containing the tubercle bacilli is discharged to reinfect the kidney at some other part and to infect the ureter and bladder. By this means the process of cure and re-infection continues, until the organ is ultimately destroyed and a so-called auto-nephrectomy results. In the meantime a systolic bladder has been produced which, despite excision of the organ, may persist and by its backward pressure ultimately destroy the renal functioning tissue of the remaining kidney and lead to death by uræmia. I have had several such cases and have tried various remedies, the most successful of which was the transplantation of the remaining ureter into the pelvic colon. It is my fervid hope that the day is not far distant when nephrectomy for renal tuberculosis will be required no longer. As it is to-day, however, if it is indicated, the surgeon operating is under an honourable obligation to care for his patient for two years afterwards, to arrange post-operative sanatorium treatment, and in certain cases to advocate pre-operative sanatorium preparatory treatment.

Transplantation of the ureters into the pelvic colon and the establishment of a cloaca.—This operative procedure that is associated especially with Stiles, Grey Turner, Coffey and Charles Mayo is now well established and is indicated in certain conditions. It is

The method I employed was first of all to make whole sections of 50 specimens that had been recently presented to the College Museum as illustrating simple prostatic hypertrophy. An interesting result followed this study where I found that 10% of these, unknown to the operator, were the site of a certain variety of carcinoma, which as we now know develops not infrequently from the simple enlargement. DISCUSSION ON THE LIFE AND DEATH OF THE RED BLOOD CORPUSCLE -

Dr. Sheila T. Callender: Our recent work on the life of the red cell has been concerned with an attempt to establish a norm for the Ashby technique by the process of bleeding and immediate transfusion of healthy volunteers. Our subjects were 6 male medical students and 4 women working in our department. They all belonged to Group A or B and were Rh positive. Details of our procedure have been described elsewhere (Callender, Powell and Witts, 1945). Two of the men have been excluded from our final results. One because he developed a small pleural effusion, presumably tuberculous, and the other because he had a transfusion reaction due to the use of a "dangerous universal donor".

In discussing our results I will deal first with the findings in men, for in the women there is the complicating factor of menstruation. In all four normal men the findings are essentially similar. An average of four counts made by two observers was taken each time, and the non-agglutinable counts were plotted against time from transfusion. The graphs fitted are practically linear, except for a short period at the beginning and end. At the beginning there is considerable irregularity of the counts and a tendency for an initial period of more rapid destruction. At the end of the graphs there is a tailing out. According to our results, however, it is not great and for practical purposes can be disregarded. We have found consistently that the average life of the transfused red cells is about sixty days and that the rate of destruction is 0.83% of the initial amount per day.

The period of initial more rapid destruction has been noted in hypochromic anæmias previously studied where the red cell count has been raised above normal, and in those normal men in whom the amount of blood given was rather more than that removed. This is of interest in relation to recent American work (Pace, Consolazio and Lozner, 1945) on transfusion as a method of producing tolerance to hypoxia in high altitude flying, and it may be one of the reasons why the observed beneficial effects were relatively short lived.

adopted in all cases of extroversion of the bladder, partial or complete. In the year 1908 Sir Harold Stiles operated on a young patient, now Mrs. X, who has her home in Fife, and is alive and in excellent health to-day. In my experience the next most important indication is the presence of an extensive vesico-vaginal fistula incapable of plastic repair, or associated with complete destruction of the vesical sphincter. The success of the operation in these cases and the relief that is produced are most impressive. On the other hand, although I have operated on many cases for malignant disease, the results have been very far from satisfactory, and I have come to the conclusion that, in these cases, there is a factor perhaps physical, perhaps psychical that tells against the success of the operation.

Reflections on the future of urology.—I regret that I must conclude with some sombre reflections. My fear for you arises from the tools you have fashioned, the skill you have shown and the dexterity you possess. Others may seek your aid, asking for your services as a technician, and not as a physician. Be warned against this insidious evil. Never examine an organ or a region, only examine a patient. Remember that medicine is an art, not a science, and that you possess many an instrument to tell you when a man is ill, but none to tell you when he is well. Man is not a motor car and susceptible to similar methods of overhaul and repair. Psychological derangements, particularly in the young female, may simulate actual organic disease. It is important to bear in mind that the final conclusions you came to when you stated a fact were not a diagnosis but a confirmed observation of the presence of an abnormality in the organ you have examined and from the limited vision of the specialist you may sincerely and honestly believe it to be the cause of ill-health; while in truth this is due to a factor outwith your knowledge. At first it would appear that the answer to this is the establishment of the Clinic or Poly-Clinic or the Health Centre, the creation of an Institution where a whole-time Staff would be available to carry out a complete investigation with all the aids known to medicine and in all the departments of medicine. In any modern rationalized surgical service the value of such an organization surely is self-evident, but is it the final answer? The premise we lay down is that the majority of ailments of which mankind complain are incapable of exact scientific demonstration. "Diagnosis", said a famous doctor, "is 50% guess work. Some guess better than others. Doctoring means sureness of personal judgment as well as brilliance in clinical assessment." To be a great urologist you must also be a great doctor and practise the art of surgery as it is seen at its best in certain fine old-fashioned general practitioners. I recall one summer morning meeting in his consulting room in the Peter Bent Brigham Hospital of the Harvard University in Boston that great surgeon, Dr. Harvey Cushing, the father of neuro-surgery; with a naughty twinkle in his eye he told me that he had just seen a case sent to him as one of pituitary tumour and it really was a case of an over-worked stenographer who required six weeks' holiday.

Health Centre.—The Health Centre may prove to be an Institution of the very greatest value. On the other hand a so-called Diagnostic Clinic may have quite a contrary effect, for it never should be forgotten that mankind is lazy and the postponement of judgment is a not uncommon way out of a difficulty. An alleged investigation may, in truth, be nothing but procrastination, a state of affairs that is peculiarly liable to develop in any service and may lead to the educated clinician developing into a collector of chits. Be not a contributor.

In discussing our results I will deal first with the findings in men, for in the women there is the complicating factor of menstruation. In all four normal men the findings are essentially similar. An average of four counts made by two observers was taken each time, and the non-agglutinable counts were plotted against time from transfusion. The graphs fitted are practically linear, except for a short period at the beginning and end. At the beginning there is considerable irregularity of the counts and a tendency for an initial period of more rapid destruction. At the end of the graphs there is a tailing out. According to our results, however, it is not great and for practical purposes can be disregarded. We have found consistently that the average life of the transfused red cells is about sixty days and that the rate of destruction is 0.83% of the initial amount per day.

The period of initial more rapid destruction has been noted in hypochromic anæmias previously studied where the red cell count has been raised above normal, and in those normal men in whom the amount of blood given was rather more than that removed. This is of interest in relation to recent American work (Pace, Consolazio and Lozner, 1945) on transfusion as a method of producing tolerance to hypoxia in high altitude flying, and it may be one of the reasons why the observed beneficial effects were relatively short lived.

Before proceeding, it will be convenient to describe the physiological implications of these results. In normal blood there is presumably a state of equilibrium between the output of new cells and the death of old ones. In using the Ashby method we have to assume that the normal subject treats his own cells and transfused normal cells alike. If this is true, we can deduce the expectation of life of the red cell from the results of the transfusion experiments. These show that, to a fair degree of approximation, the destruction of the cell is due to its own ageing and not to external factors acting independently. Leaving out the intermediate syllogisms, we find that a linear decay curve implies that the red cells live for a nearly constant time, 120 days from their birth. The average life after transfusion is half this—60 days, since the transfused cells are of all ages and have already lived 60 days on the average. There is, of course, some scatter about this value, but according to our results the effect of this is not large in comparison with the experimental error.

The women present a slightly different problem. At each menstrual period a fraction of the cells transfused will be lost, and one might expect the graph, instead of being practically linear, as in the men, to be stepped (fig. 1, solid line). If the menstrual loss

FIG. 1.—Theoretical effect of menstrual loss on the graph of survival of transfused red cells.

were sufficiently large, we might expect the periodicity to be evident on our graphs. With a relatively small loss the method is not sufficiently accurate to reveal the periodicity, but the effect will be to produce a greater curvature than that found in the males (fig. 1, dotted line). The difference between this curve and the male graph should give an estimate of the menstrual loss, if this is the only difference in treatment of transfused cells between males and females. Our female volunteers (4) did in fact give curved graphs though, as expected, the longest time of survival of cells was, as in the males, fairly sharply defined at about 120 days. Thus it seems likely that the inherent limitation of the life span is constant and that marked curvature is due to non-selective loss of blood by hæmolysis or hæmorrhage.

The calculated menstrual loss from the difference between the average of the male and female curves is 300 to 400 c.c. per period. This is, of course, extremely large. Other methods have given a loss of about 7 c.c. to 180 c.c. per period (Widdowson and McCance, 1942; Barer and Fowler, 1936). Our calculation is not really warranted by the accuracy of our methods, and the estimate may easily be in error by 50%. Also, if there had been any post-transfusion hæmolysis this would not have been separately detected, but might have accounted for a considerable proportion of the curvature in the survival graphs. Further studies are necessary to prove whether the difference between males and females is entirely accounted for by blood loss of menstruation, or whether perhaps there is an additional factor such as one related to ovarian secretion.

As far as we have gone, our work has shown that the maximum life of transfused red cells in the normal subject is about 120 days in both males and females. There is presumptive evidence that the life of any individual's own red cells, apart from the effects of hæmolysis or blood loss, is 120 days, and that the main factor determining the disappearance of any cell is its age.

Dr. J. F. Loutit: The Ashby technique for following the survival of transfused red cells was in the past adversely criticized because of irregularities in the graphs of the red cell survival. Recent modifications and improvements have, however, resulted in a method which gives consistent and reproducible results. Extremely powerful agglutinating sera must be used; care must be taken to exclude non-specific agglutination; and the red cells of the recipient must be of high sensitivity for agglutination. Under these circumstances, as Dr. Callender has pointed out, the method gives a figure for the life-span of the normal red cell which is in agreement with that obtained recently by other methods. The subject has been summarized in two leading articles [1, 2] in British journals and one special article in the U.S.A. [3].

In contrast with Dr. Callender's account of the life-span of transfused normal red cells in normal recipients, I propose to discuss the survival of transfused normal red cells in recipients with hypochromic anaemia, Addisonian anaemia and acholuric jaundice, both congenital and acquired. I will discuss also the survival of red cells transfused from donors with Addisonian anaemia and acholuric jaundice to normal recipients. Some of these results are drawn from published works; the rest are results obtained at the South London Blood Supply Depot and are unpublished or are in process of publication. My colleagues, especially Lieut.-Colonel P. L. Mollison, have been responsible for much of the work.

Hypochromic anaemia.—In 1944 Brown, Hayward, Powell and Wits [4] studied, by the Ashby technique, the survival of transfused normal red cells in 6 cases of idiopathic hypochromic anaemia. Their results showed that the decay graph was nearly linear, indicating a nearly constant rate of destruction with an average life of the transfused red cell of just over 50 days. This corresponds with a life-span for the red cell of something over 100 days.

Very similar figures had been obtained in 1942 by Mollison and Young [5]. 15 cases of anaemia from hæmorrhage were transfused with fresh blood. The maximum survival time of the transfused red cells averaged 105 days.

It should be noted that these results only indicate the life of *normal* red cells. They give no indication of the life-span of the patients' *own* red cells.

Addisonian anaemia.—Ashby [6] herself in 1921 was able to follow to completion or near completion the survival of transfused group O red cells in 4 group A recipients with pernicious anaemia. In two of the cases elimination of the transfused red cells appeared to be complete by the 91st and 100th day respectively. In the other two, elimination was not quite complete at the 83rd and 100th day. Wearn, Warren and Ames in 1922 [7] repeated the experiment in 4 recipients with pernicious anaemia and state that the transfused red cells survived for a surprisingly long time, namely 59 to 113 days. The results of Ashby and Wearn *et al.* were obtained before the institution of liver treatment and therefore represent results in what we would now call "untreated" cases. In 1944 Brown *et al.* [4] noted one case of true Addisonian anaemia responding to liver and showed that the survival of the transfused red cells was of the normal linear type.

I have had the opportunity of transfusing with blood stored in acid citrate-glucose solution 5 cases of true Addisonian anaemia responding to liver and following the survival of the transfused red cells. Most of these cases have not been sampled sufficiently often for me to be dogmatic about the maximal or average red cell life of the transfused red cell, but qualitatively the survival was not grossly abnormal. Fig. 1 shows the graphs of the survival of the transfused red cells in the 5 cases. Even if one excludes the case given 14-day-old blood, the others given blood stored from two to seven days show a 50% survival of the transfused red cells at 31, 35, 43 and 53 days respectively (mean 40.5 days). This is rather less than the corresponding figure of 60 days obtained by Mollison and Young for blood 0 to 4 days' old in the 15 recipients with hypochromic anaemia.

On the other hand, when two convalescent subjects with mild hypochromic anaemia from hæmorrhage were transfused with blood from untreated cases of pernicious anaemia, a different graph of elimination was obtained. The pernicious anaemia donor red cells were destroyed rapidly, 50% survival occurring at about the 10th and 12th days respectively (fig. 2).

Until the discovery of the rôle of the liver principle in pernicious anaemia, the anaemia was considered to be of hæmolytic type. Subsequently, it was thought to be purely

Before proceeding, it will be convenient to describe the physiological implications of these results. In normal blood there is presumably a state of equilibrium between the output of new cells and the death of old ones. In using the Ashby method we have to assume that the normal subject treats his own cells and transfused normal cells alike. If this is true, we can deduce the expectation of life of the red cell from the results of the transfusion experiments. These show that, to a fair degree of approximation, the destruction of the cell is due to its own ageing and not to external factors acting independently. Leaving out the intermediate syllogisms, we find that a linear decay curve implies that the red cells live for a nearly constant time, 120 days from their birth. The average life after transfusion is half this—60 days, since the transfused cells are of all ages and have already lived 60 days on the average. There is, of course, some scatter about this value, but according to our results the effect of this is not large in comparison with the experimental error.

The women present a slightly different problem. At each menstrual period a fraction of the cells transfused will be lost, and one might expect the graph, instead of being practically linear, as in the men, to be stepped (fig. 1, solid line). If the menstrual loss

FIG. 1.—Theoretical effect of menstrual loss on the graph of survival of transfused red cells.

were sufficiently large, we might expect the periodicity to be evident on our graphs. With a relatively small loss the method is not sufficiently accurate to reveal the periodicity, but the effect will be to produce a greater curvature than that found in the males (fig. 1, dotted line). The difference between this curve and the male graph should give an estimate of the menstrual loss, if this is the only difference in treatment of transfused cells between males and females. Our female volunteers (4) did in fact give curved graphs though, as expected, the longest time of survival of cells was, as in the males, fairly sharply defined at about 120 days. Thus it seems likely that the inherent limitation of the life span is constant and that marked curvature is due to non-selective loss of blood by hæmolysis or hæmorrhage.

The calculated menstrual loss from the difference between the average of the male and female curves is 300 to 400 c.c. per period. This is, of course, extremely large. Other methods have given a loss of about 7 c.c. to 180 c.c. per period (Widdowson and McCance, 1942; Barer and Fowler, 1936). Our calculation is not really warranted by the accuracy of our methods, and the estimate may easily be in error by 50%. Also, if there had been any post-transfusion hæmolysis this would not have been separately detected, but might have accounted for a considerable proportion of the curvature in the survival graphs. Further studies are necessary to prove whether the difference between males and females is entirely accounted for by blood loss of menstruation, or whether perhaps there is an additional factor such as one related to ovarian secretion.

As far as we have gone, our work has shown that the maximum life of transfused red cells in the normal subject is about 120 days in both males and females. There is presumptive evidence that the life of any individual's own red cells, apart from the effects of hæmolysis or blood loss, is 120 days, and that the main factor determining the disappearance of any cell is its age.

dyshaemopoietic and that the haemosiderosis of the organs, the hyperbilirubinemia and the increased bilirubinoid pigment excretion were due to the failure of the body to use the by-products of red-cell destruction as occurs in normal erythropoiesis. If, however, my results of the survival of pernicious anaemia red cells in convalescent subjects can be applied to the survival of the same cells in the subjects from which the blood was drawn (that is cases of pernicious anaemia), then an undue haemolysis in the peripheral blood of cases of pernicious anaemia does occur and no other explanation is needed for the haemosiderosis and the hyperbilirubinemia. Wearn, Warren and Ames [7] did try to follow the survival of the red cells of one case of pernicious anaemia in the circulation of another case of pernicious anaemia, but the protocol of their results is not convincing. My conception, therefore, is that the red cells of pernicious anaemia cases are discharged from the marrow with faulty protoplasm, due to the liver principle deficiency, and being faulty are as unduly susceptible to destruction in the circulation of pernicious anaemia cases as in a "normal" person.

Acholic jaundice.—The term acholic jaundice is used in this country for cases of haemolytic anaemia whose red cells manifest pronounced increased saline fragility and spherocytosis. A congenital and familial form (Minkowski and Chauffard) is the common type and its existence is well established. An acquired form (Hayem and Vidal) has been postulated but not universally accepted. Our work confirms that these two types do exist and are of a different aetiology.

Dacie and Mollison (1943) [8] transfused 6 cases of the congenital type with fresh normal blood. Fig. 3 shows the results of the survival in 5 of these cases, the maximal cell life of the transfused red cells was 100–120 or more days with a 50% survival averaging 54 days.

Mollison and I have transfused with fresh blood 8 cases of acquired acholic jaundice. Fig. 4 shows the graph of the red cell survivals in two of these cases. In all these cases the maximal red cell life of the transfused red cells was grossly diminished and a 50% survival was obtained at the 1st to 28th day with a mean at 6.3 days for 10 transfusions carried out before splenectomy. In 4 of these cases 5 transfusions with red cell survival estimations were carried out after splenectomy. 50% survival was noted on the 1st to the 9th day with a mean at the 5th day—this in spite of the fact that many of the cases were markedly improved in that red cell counts and haemoglobin figures returned to normal, though the increased red cell fragility and spherocytosis persisted. One case

FIG. 1.—Disappearance of Sulphamoglobin (—) and of Methamoglobin (---) from the circulating blood of TNT workers after their withdrawal from contact with TNT. The different symbols correspond to the seven workers studied.

The most serious of these assumptions is (2). SHb formation probably does go on to some extent for a few days after cessation of contact with the toxic agent, and this introduces some uncertainty into the estimate of the true starting point of the decay curve, though it probably does not affect more than the first five to ten days at the most. This matter requires further detailed study. (5) is important in comparing these results with those from other methods of estimating red cell life: however, formation of SHb within a red cell might be expected to curtail rather than lengthen its life, and this value of 116 days is considerably greater than the value of 30-50 days which has until recently been accepted.

These conclusions as to the average life span of the red cells containing SHb, and the linearity of decay curve, are in close agreement with those of Callender, Powell and Wits (1945) put forward above by Dr. Callender. Recently also Shemin and Rittenberg (1945) have studied the incorporation of the N^{15} isotope from ingested glycine into the protoporphyrin of haemoglobin, and its subsequent disappearance, and have concluded that the life span of the red cell must be greater than 100 days. Their data also are consistent with the linear decay hypothesis. It is to be hoped they will extend these experiments long enough, about 160 days, to provide a more detailed test of the above conclusions.

The differential agglutination method, employed by Callender, Powell and Wits, and the SHb method are complementary; in the former destruction of normal red cells can be followed, but not that of the subject's own cells, while in the latter the destruction of the subject's own cells is followed, though having SHb formed within them they cannot be regarded as perfectly normal. Moreover, the agglutination method is based upon a property of the red cell envelope, and the SHb method upon a property of the cell contents. It is therefore particularly significant that they should lead to a similar result for both shape of decay curve and life span.

The three approaches discussed above all give information concerning the dynamics of red cell destruction, whereas most earlier approaches to the problem of red cell life merely yielded an estimate of the average life, with no information as to the shape of

Our conception, therefore, is that the red cells of cases of congenital acholuric jaundice are abnormal due to an inborn defect of the red cell as postulated by Naegeli (1931) [9]. This would explain their abnormal survival in a normal circulation and the normal survival of normal red cells in the circulation of cases of congenital acholuric jaundice. In acquired acholuric jaundice we (Boorman *et al.*, 1946) [10] agree with Dameshek and Schwartz (1938) [11] that there is a circulating hæmolysin. This destroys transfused red cells as well as the patient's own red cells. The red cells of cases of acquired acholuric jaundice are, therefore, "sensitized". The substantially normal survival of these "sensitized" red cells in a normal circulation, though at first sight surprising, is not unique: we have been able *in vitro* to sensitize red cells which when subsequently transfused were shown to survive in a normal recipient in a fashion similar to normal red cells.

Dr. E. M. Jope: *The disappearance of sulphæmoglobin from circulating blood in relation to red cell destruction.*—Methæmoglobin (MHb) disappears rapidly from circulating blood after the causative agent (TNT, sulphonamides, &c.) has been removed, being usually no longer detectable after about two to five days; in drawn blood kept at room temperature it may disappear in as little as twenty-four hours. This reversion to functional hæmoglobin is arrested by iodoacetate or fluoride ions and is probably coupled to the similarly inhibited reducing systems of the intact red cell, such as glycolysis (Drabkin, 1945). Continued raised levels of MHb in toxic cyanoses must be due to preponderance of toxic oxidative processes over the intracellular reducing processes. By contrast sulphæmoglobin (SHb) persists in circulating or drawn blood for many weeks. It appears therefore that the red cell has no means within it of transforming SHb, and if this is so it follows that the body can have no means of removing SHb other than by destruction of the red cells that contain it. The disappearance of SHb from the circulating blood of seven cyanosed TNT workers was accordingly studied in an attempt to follow the dynamics of this red cell destruction.

This work was made possible by the co-operation of Drs. H. K. Tucker and Helen Ramsay, and of Dr. A. J. Amor, at the time Chief Medical Officer of the Ministry of Supply, who arranged for the work to be carried out at a Ministry of Supply establishment.

The plots of the SHb levels of these workers' bloods against the time in days after their removal from contact with TNT were well fitted by the straight line (fig. 1):—

SHb (% of total pigment) = $96 - 0.83$ (days subsequent to removal from TNT contact).

This expression gives a value for zero SHb of 116 (± 5) days (fig. 1). This may be considered as an estimate of the life span of the red cells containing SHb upon the following assumptions: (1) That the intact red cell possesses no means of transforming SHb and that the body has no means of removing it other than removal of the red cells which contain it. (2) That no significant SHb formation goes on after administration of the apparent causative agent has ceased. (3) That neither SHb nor the heme part of its molecule are incorporated into new red cells.

In relating the destruction of red cells containing SHb to that of normal red cells two further assumptions must be made: (4) That the SHb is formed at random in red cells of all ages existing in the body. (5) That formation of SHb within the red cell does not prolong or curtail its life.

Peculiarities in the Pathology of Cancer of the Ano-Rectal Region

By CUTHBERT E. DUKES, M.D., M.Sc., D.P.H.

Pathologist to St. Mark's Hospital, London

MALIGNANT tumours which are situated partly in the rectum and partly in the anal canal often exhibit features of special surgical interest. In the first place the clinical diagnosis is often difficult, especially in the early stages of malignancy. Then the question arises as to whether a malignant tumour is a columnar-celled carcinoma extending down from the rectum or a squamous-celled carcinoma spreading up from the anal canal. This can be settled by biopsy but the microscopic examination of sections of tumours from this region not infrequently reveals an unexpected type of neoplasm. Tumours which arise at a mucocutaneous junction in any part of the body tend to be a "mixed bag" and the ano-rectal region is no exception to the rule. For all these reasons I thought it would be of interest to make a survey of the pathology of cancer of the ano-rectal region, so I have analysed the facts revealed by the pathological examination of 203 consecutive cases treated by radical excision at St. Mark's Hospital. In each case the malignant growth was situated partly in the rectum and partly in the anal canal.

SEX AND AGE DISTRIBUTION

It is well known that cancer of the rectum is commoner in men than in women, and in a series of 1,000 cases recently analysed there were 65% males and 35% females. A similar peculiar sex distribution is noticed also in ano-rectal cancers. In this series of 203 cases there were 62% males and 38% females. The average age at the time of diagnosis was 58 years, approximately the same as that for rectal cancers in general.

GROSS CHARACTERS OF PRIMARY TUMOURS

In their size, shape and other gross characters most malignant tumours of the ano-rectal region do not differ to any appreciable extent from those situated at a higher or lower level in the bowel, but occasionally a primary tumour in the ano-rectal region may be almost unrecognizable by clinical examination alone. This applies particularly to cases of colloid carcinoma associated with fistula. It is important to remember that a malignant growth may extend deeply along the track of a fistula without forming a recognizable tumour within the lumen of the bowel. Two such cases were observed in this series. In each of these colloid carcinoma had extended along the tracks of fistulae into the ischio-rectal fat without producing a recognizable tumour in the rectum or anal canal. In a third case which appeared at first to be of a similar character, the growth was found to be a teratoma. This was derived from the sacral region and produced a large mass of firm tissue containing cysts, situated between the sacrum and rectum.

So much for carcinoma associated with fistulae, but colloid carcinoma may behave in a strange way, even when fistulae are not present. In one case in this series the only visible growth was an inconspicuous linear ridge extending upwards for about an inch in the posterior quadrant of the lower third of the rectum. But though there was little to see there was plenty to feel, and when the patient was examined by Mr. W. B. Gabriel he could palpate a cord of hard tissue extending along the course of the hæmorrhoidal vessels. Subsequent microscopic examination showed this to be due to continuous permeation of the lymphatic channels accompanying the hæmorrhoidal vessels. Although the primary tumour was so small 12 out of 15 glands contained metastases. In another case of colloid carcinoma the primary growth took the form of a narrow fissure surrounded by clusters of nodules, mostly situated in the submucosa at a higher level. In this case also there was widespread permeation of all the lymphatic channels accompanying the hæmorrhoidal vessels and every lymphatic gland seen contained metastases.

HISTOLOGY OF ANO-RECTAL MALIGNANT DISEASE

Turning now from the gross characters of tumours of the ano-rectal region to their microscopic structure we find several points of special surgical interest. In the first place the surgeon wishes to know whether the growth is a columnar-celled or a squamous-celled carcinoma. The former is much the commoner. In this series of 203 tumours no less than 188, or more than 90%, were columnar-celled or adenocarcinomas which had extended down from the rectum and begun to trespass into the anal canal. Only seven were pure squamous-celled growths extending up from below. In five other cases the tumour was of mixed histology, the upper part being adenocarcinoma and the lower squamous.

Even by careful inspection of these mixed tumours one cannot recognize any difference

the decay curve. The linear decay curve implying a fixed life span for the red cell of about 120 days seems well established by these three experimental procedures. This is considerably longer than the values of about 30-50 days in man usually derived from earlier methods. The more recent work has the advantage of giving information as to the shape of the decay curve as well as an estimate of the life span, and it is difficult to explain the linear decay except in terms of non-random red cell destruction. Earlier methods based upon the assumption that an estimate of hæmoglobin breakdown could be derived from bile pigment estimations suffer from the general disadvantage that muscle hæmoglobin makes an unknown contribution to this output. Reticulocyte methods seem full of difficulties, particularly of basic definitions. It seems that the most reasonable estimate of red cell life span is given by the results of differential agglutination, SHb, and N^{15} isotope methods, published during the past eighteen months.

It would be valuable to apply the SHb method to the study of red cell destruction in animals, where the blood sub-groups are not sufficiently specific for the differential agglutination method to be employed. SHb can be formed with some certainty in the rabbit or rat by feeding with sulphur and acetanilide or phenacetin (Michel, 1938; Lemberg *et al.*, 1942), but large doses given over a short period with the intention of producing sudden high concentrations of SHb are liable to produce also another pigment, choleglobin, which may confuse the most precise attempts at spectrophotometric estimation of SHb unless suitable precautions are taken. Choleglobin has not so far been encountered in human sulphæmoglobinæmia due to TNT, sulphonamides or phenacetin, but the SHb levels are comparatively low, usually below 7% of total pigment.

In the present work SHb has been estimated spectrophotometrically. For such estimations it is imperative to work with perfectly transparent solutions, and all turbidity was removed from the whole blood dilutions by vigorous centrifugation. Turbidity can be particularly persistent in blood from cyanosed subjects, and Horecker (1944) has shown this to be due in the case of MHb to an accumulation of denatured globin within the red cells.

This work was supported by a grant from the Medical Research Council, and is published fully elsewhere (Jope, 1946).

tumour was found in material removed for biopsy during sigmoidoscopic examination and sent to the laboratory for diagnosis.

These six cases were scattered over the decade 1926 to 1946. The first patient was a woman aged 40 who attended the Out-patient Department of St. Mark's Hospital in 1936. A small nodular carcinoid tumour was removed from the lower third of the rectum just above the ano-rectal line, but I have not been able to get in touch with this patient again and can only say that she never returned to the hospital. The next case occurred in 1937, the patient being a woman aged 34 who was also found to have a small nodular carcinoid tumour in the lower third of the rectum. This was removed by local excision and I am glad to say that now, nine years later, her health is good and there has been no sign of recurrence. Two cases were met with in 1940, one in a man aged 40 who died one year later from other causes, the other in a woman aged 36 whom I have been unable to trace. One case was met with in 1945 and one in 1946.

The questions which have to be decided with regard to carcinoid tumours are (1) do they require any surgical treatment at all? and (2) if they are removed are they liable to recur? These questions can only be answered when a larger number of cases has been kept under observation for a longer period of time. At the present time the best advice a pathologist can give to a surgeon is to remove a carcinoid tumour by local excision and to keep the patient under observation and watch for any sign of recurrence. The real danger about carcinoid tumours is that they might be mistaken for carcinomas. This mistake is more likely to be made by a pathologist than by a surgeon because in its gross characters a carcinoid tumour does not look like a malignant tumour, whereas in its microscopic structure it does.

I have mentioned a number of peculiarities in the surgical pathology of malignant disease of the ano-rectal region, some of which are of trivial character and some of more importance. I should like as a final word to recall the four features which seem to me to be most worthy of emphasis, namely (1) the association of colloid carcinoma with a fistulous track; (2) the fact that a very small primary tumour in the ano-rectal region may have spread far and wide; (3) the observation that tumours of the ano-rectal region may be of a mixed character, the upper part being columnar and the lower squamous-celled carcinoma; (4) the occasional presence in the ano-rectal region of a carcinoid tumour of doubtful malignancy and the importance of distinguishing this from ordinary carcinoma.

A Brief Surgical Review of 201 Malignant Growths of the Ano-Rectal Region

By C. NAUNTON MORGAN, F.R.C.S.

[In absentia read by W. I. CAWKWELL, F.R.C.S.]

PERINEAL excision is still regarded by some surgeons as the operation of choice for growths of the rectum above which a *finger can be passed*, i.e. growths of the lower third. If this operation is to be considered a radical procedure for malignant neoplasms of the lower rectum, then those situated in the ano-rectal region should be amongst the most suitable. An opportunity has arisen for study of growths at this level of the bowel from the surgical aspect, at a time when Dr. Dukes has reviewed their pathology.

In order to obtain some concrete information regarding the best operation for eradication of ano-rectal malignant neoplasms, their surgical pathology has been studied from 201 pathological reports, scale drawings and photographs of specimens removed either by combined or perineal excision. Amongst this number were 12 squamous-celled growths, which included the mixed type already described by Dukes.

Indications for the less severe operation of perineal excision for reasons of associated disease, poor general health or as a palliative measure are not here considered, though of course these factors and especially the familiarity of the surgeon with the operation of combined excision may enter into the choice of operation.

Apart from the demonstration of lymphatic spread by dissection and microscopy of the excised specimen, accurate information regarding the suitability of the case for one or other operation is not always easily obtained. Nevertheless, an unbiased attempt has been made to assess the clinical and operative problem from the *pathological data alone*.

Combined excision is necessary for radical surgery in all growths with extensive lymphatic involvement, for those with a second malignant neoplasm several inches higher up in the rectum or where there is a submucous spread. In the large majority of instances, the degree of lymphatic implication is unknown to the surgeon; only occasionally are the full facts known before operation.

It was found on the grounds mainly of high lymphatic spread, the presence of a second growth or of submucous infiltration that about *one-half of the examined specimens* could only have been radically treated by *combined excision*.

In addition to the above findings, either alone or in association, there were other factors which called for a more radical removal than that which perineal excision can offer.

between the epithelial constituents of the growth. In two cases there were no lymphatic metastases, but in one there was evidence of venous spread. In the two cases with lymphatic metastases, some metastases were squamous and others adenocarcinoma in type.

The most probable explanation of these mixed tumours is that they are formed by the fusion of two separate malignant growths, one of which arose above and the other below the ano-rectal line. Most recent studies go to show that in their earliest phases malignant tumours are often multifocal in origin. As these small initial foci of malignant growth enlarge they fuse together making one single tumour. In these mixed tumours the parts arising above and below the ano-rectal line retained the distinctive histological features of their site of origin, although now compounded together into one single tumour.

Columnar and squamous-celled carcinomas are the commonest manifestations of malignancy in the ano-rectal region but other varieties of malignant tumour may also occur; in fact, this mucocutaneous junction may be described as fertile soil for pathological curiosities. A transitional cell type of carcinoma is by no means rare. Melanoma, lymphosarcoma, fibrosarcoma and teratoma seem to be commoner in this situation than elsewhere in the rectum or anal canal. These rarer malignant tumours often exhibit some feature which makes the surgeon suspect that he is dealing with something out of the ordinary, but this is not always the case. No doubt in their earliest phases the rarer forms of malignancy do exhibit characteristic distinguishing features, but at a later stage, especially when the surface has become ulcerated and infected, nothing but microscopic examination can distinguish sarcoma from carcinoma.

The surgical treatment of all the forms of malignancy so far mentioned is the same, namely prompt and radical excision, but what is the appropriate treatment for a tumour of doubtful malignancy, such as a carcinoid? Surgeons are of course familiar with carcinoid tumours in the appendix and it is well known that they are of a low grade malignancy, grow slowly and seldom give rise to lymphatic metastases. It is not generally known that carcinoid tumours may occur so far afield as the ano-rectal region but I have come across nine cases in which a small tumour with the characteristic histology of a carcinoid was found in the ano-rectal region or lower third of the rectum.

The special characteristics of carcinoid tumours.—They are known also as pseudo-carcinomas, small-celled carcinoma or argentaffine tumours. The last name is used because it has been shown that they are derived from specially differentiated cells of the intestinal epithelium which have an affinity for silver salts. These argentaffine cells occur normally in small clusters in the cardiac and pyloric regions of the stomach and in the duodenum, and are found also in much smaller numbers in the small intestine and colon. These specialized intestinal cells often contain yellow granules which can be recognized by microscopic examination of the unstained paraffin sections and they may also be made to emit a bright yellow fluorescence. The exact function of argentaffine cells is unknown but it has been supposed that they are the source of an internal secretion. Since the distribution of argentaffine cells shows a close parallelism with the localization of the active principle against pernicious anemia it has been suggested that they may be a source of the hæmopoietic principle. Thus in twelve cases of pernicious anemia studied by Jacobson in 1939 (Jacobson, W., *J. Path. Bact.*, 1939, 49, 1) the argentaffine cells were either completely, or almost completely, absent. In two cases of sprue with macrocytic anemia an almost complete absence of argentaffine cells was also noted, whereas in other blood diseases no change was found from the normal distribution of argentaffine cells.

Carcinoid tumours derived from argentaffine cells are fairly common in the appendix but rare elsewhere. They take the form of small nodules embedded in the mucous membrane or submucosa. They are often multiple, seldom ulcerate and rarely metastasize. Even when metastases have been known to be present patients have been reported to remain alive and well for more than eight years.

Microscopic examination shows these tumours to consist of closely packed, small, round or oval cells with round, deeply-staining nuclei. The tumour cells are generally arranged in small clusters but may show a glandular arrangement. Often the tumour appears to be encapsulated but the stroma may contain smooth muscle fibres. The complete identification of a carcinoid tumour requires the demonstration of argentaffine granules in the tumour cells, but most pathologists are agreed that the histological structure is sufficiently distinctive to permit diagnosis without the use of a silver stain.

The nine cases of carcinoid tumours of the ano-rectal region which I have come across all had the form of small firm rather solid nodules situated in the mucous membrane and submucosa. They resembled small adenomas or lymphomas and did not look like malignant growths. The first three were accidental findings noticed during the routine examination of an operation specimen of rectal cancer. The question of further surgical treatment did not arise in these first three cases because the tumours were only accidentally discovered in an organ already removed from the patient, but in the other six patients a carcinoid

tumour was found in material removed for biopsy during sigmoidoscopic examination and sent to the laboratory for diagnosis.

These six cases were scattered over the decade 1926 to 1946. The first patient was a woman aged 40 who attended the Out-patient Department of St. Mark's Hospital in 1936. A small nodular carcinoid tumour was removed from the lower third of the rectum just above the ano-rectal line, but I have not been able to get in touch with this patient again and can only say that she never returned to the hospital. The next case occurred in 1937, the patient being a woman aged 34 who was also found to have a small nodular carcinoid tumour in the lower third of the rectum. This was removed by local excision and I am glad to say that now, nine years later, her health is good and there has been no sign of recurrence. Two cases were met with in 1940, one in a man aged 50 who died one year later from other causes, the other in a woman aged 36 whom I have been unable to trace. One case was met with in 1945 and one in 1946.

The questions which have to be decided with regard to carcinoid tumours are (1) do they require any surgical treatment at all? and (2) if they are removed are they liable to recur? These questions can only be answered when a larger number of cases has been kept under observation for a longer period of time. At the present time the best advice a pathologist can give to a surgeon is to remove a carcinoid tumour by local excision and to keep the patient under observation and watch for any sign of recurrence. The real danger about carcinoid tumours is that they might be mistaken for carcinomas. This mistake is more likely to be made by a pathologist than by a surgeon because in its gross characters a carcinoid tumour does not look like a malignant tumour, whereas in its microscopic structure it does.

I have mentioned a number of peculiarities in the surgical pathology of malignant disease of the ano-rectal region, some of which are of trivial character and some of more importance. I should like as a final word to recall the four features which seem to me to be most worthy of emphasis, namely (1) the association of colloid carcinoma with a fistulous track; (2) the fact that a very small primary tumour in the ano-rectal region may have spread far and wide; (3) the observation that tumours of the ano-rectal region may be of a mixed character, the upper part being columnar and the lower squamous-celled carcinoma; (4) the occasional presence in the ano-rectal region of a carcinoid tumour of doubtful malignancy and the importance of distinguishing this from ordinary carcinoma.

A Brief Surgical Review of 201 Malignant Growths of the Ano-Rectal Region

By C. NAUNTON MORGAN, F.R.C.S.

[In absentia read by W. I. CAWKWELL, F.R.C.S.]

PERINEAL excision is still regarded by some surgeons as the operation of choice for growths of the rectum above which a finger can be passed, i.e. growths of the lower third. If this operation is to be considered a radical procedure for malignant neoplasms of the lower rectum, then those situated in the ano-rectal region should be amongst the most suitable. An opportunity has arisen for study of growths at this level of the bowel from the surgical aspect, at a time when Dr. Dukes has reviewed their pathology.

In order to obtain some concrete information regarding the best operation for eradication of ano-rectal malignant neoplasms, their surgical pathology has been studied from 201 pathological reports, scale drawings and photographs of specimens removed either by combined or perineal excision. Amongst this number were 12 squamous-celled growths, which included the mixed type already described by Dukes.

Indications for the less severe operation of perineal excision for reasons of associated disease, poor general health or as a palliative measure are not here considered, though of course these factors and especially the familiarity of the surgeon with the operation of combined excision may enter into the choice of operation.

Apart from the demonstration of lymphatic spread by dissection and microscopy of the excised specimen, accurate information regarding the suitability of the case for one or other operation is not always easily obtained. Nevertheless, an unbiased attempt has been made to assess the clinical and operative problem from the *pathological data alone*.

Combined excision is necessary for radical surgery in all growths with extensive lymphatic involvement, for those with a second malignant neoplasm several inches higher up in the rectum or where there is a submucous spread. In the large majority of instances, the degree of lymphatic implication is unknown to the surgeon; only occasionally are the full facts known before operation.

It was found on the grounds mainly of high lymphatic spread, the presence of a second growth or of submucous infiltration that about *one-half of the examined specimens* could only have been radically treated by *combined excision*.

In addition to the above findings, either alone or in association, there were other factors which called for a more radical removal than that which perineal excision can offer.

between the epithelial constituents of the growth. In two cases there were no lymphatic metastases, but in one there was evidence of venous spread. In the two cases with lymphatic metastases, some metastases were squamous and others adenocarcinoma in type.

The most probable explanation of these mixed tumours is that they are formed by the fusion of two separate malignant growths, one of which arose above and the other below the ano-rectal line. Most recent studies go to show that in their earliest phases malignant tumours are often multifocal in origin. The complete identification of a carcinoid tumour requires the demonstration of argentaffine granules in the tumour cells, but most pathologists are agreed that the histological structure is sufficiently distinctive to permit diagnosis without the use of a silver stain.

The nine cases of carcinoid tumours of the ano-rectal region which I have come across all had the form of small firm rather solid nodules situated in the mucous membrane and submucosa. They resembled small adenomas or lymphomas and did not look like malignant growths. The first three were accidental findings noticed during the routine examination of an operation specimen of rectal cancer. The question of further surgical treatment did not arise in these first three cases because the tumours were only accidentally discovered in an organ already removed from the patient, but in the other six patients a carcinoid

or whether it seemed that both the cæcum and the appendix were involved in the same simultaneous pathological process. This decision does not create much difficulty for the previous experience of acute appendicitis teaches the surgeon to assess the condition of the cæcum which is compatible with that diagnosis.

If it were decided that the case was one of amœbic infection then the appendix was never removed but the abdomen closed perhaps with a soft corrugated drain for seventy-two hours but never around a hard tube the pressure of which might cause ulceration. Specific anti-dysenteric treatment was instituted immediately.

This routine proved satisfactory and was not varied.

I saw five cases of perforation of the cæcum or colon due to dysentery. One formed a pericolic abscess, and after drainage survived with a temporary faecal fistula. The other four died and two of them never even reached the operating theatre. Indeed with an occasional exception the condition must be recognized as uniformly fatal. The time factor is of supreme importance and wherever possible the affected loop should be brought out as a colostomy and the peritoneal cavity drained. Where the perforation occurs in a fixed portion of the colon it can only be closed and covered with omentum. The difficulty of making such sutures hold has already been emphasized. Routine treatment by intravenous infusion, continuous gastric suction and chemotherapy is added to the emetine injections, but the outlook is depressing.

The only variety of strictures of the rectum and colon following dysentery which occurred with any frequency was one situated at a constant level two inches above the anal canal. This site I assumed to be the lowest valve of Houston. Confirming this, the early cases showed a crescentic outline only later spreading to become annular and diaphragmatic and lastly extending longitudinally to involve an inch of rectal wall.

The level at which these strictures occur contrasts sharply with my observations as to the site at which the lowest lesion tends to persist in amœbic dysentery, which I found to be five and a half inches from the anal canal. The question had arisen whether proctoscopy was of appreciable help in diagnosing difficult cases of amœbic dysentery or whether sigmoidoscopy was necessary. I held the view that a sigmoidoscope was needed because from my case records the lowest site at which a solitary amœbic ulcer commonly persisted was five and a half inches above the anal canal.

This finding is obviously not an absolute one for Manson-Bahr has recorded two cases of solitary amœbic ulcer of the rectum within reach of the finger. Amœbic ulceration is frequently to be seen through a proctoscope but in such cases there is no difficulty in finding the entamœbæ in the stools and the proctoscopy is of academic interest only. I did not find that these low amœbic ulcers tended to persist. Therefore in spite of the fact that four of my stricture cases were stated to have had amœbic dysentery I am of the opinion that where a rectal stricture is attributable to dysentery it is the result of bacillary infection and it cannot be expected to respond to any specific therapy.

In my cases of amœbic dysentery two localized narrowings of the colon occurred. One was due to an amœbic granuloma, and the other to pericolicitis with abscess formation. It is clear that in either condition healing might progress to infiltration of the bowel wall with subsequent stenosis or stricture.

There now remains for comment the conditions of amœbic hepatitis and amœbic abscess and there is no clear demarcation between the two. For this reason the initial treatment is by emetine. The response is dramatic and in the majority of cases clinical recovery is complete. It is not generally agreed whether these successes include any true liver abscesses. Personally I think they do, for I have seen many cases showing all the signs of abscess formation including that of "cupping" or "tenting" of the diaphragm, but which have responded within twelve days to the emetine injections. I believe that the absorption of pus may take place if the following criteria are fulfilled: (1) The abscess is small (less than 4 oz. of pus). (2) It is situated posteriorly in the right lobe of the liver. (3) It is not secondarily infected. Obviously medical treatment cannot bring about a cure in the presence of secondary infection.

The figure of 4 oz. is empirical, and I quote it because aspiration of cases which have failed to respond to emetine usually yield more than 4 oz. of pus. I find that a higher percentage of anterior abscesses require aspiration and, following on this, a higher percentage of anterior abscesses eventually need open drainage when compared with those situated posteriorly.

In brief the treatment of hepatic amœbiasis is by medical means. Aspiration is reserved for cases in which the general condition deteriorates during the injections and those which fail to respond to the full course. Open drainage is undertaken for abscesses which recur after repeated aspiration.

Where the site could be determined by X-ray, local tenderness or bulging of the chest wall, posterior abscesses were aspirated directly over the swelling. Purely exploratory puncture was performed systematically through the lowest three intercostal spaces which

A large and bulky growth of this region will not only prevent accurate examination of the rectum and rectosigmoid above it, but furthermore the mechanical difficulties may make its removal with high division of the mesorectum impossible. Fixity of the growth and infiltration of other structures, especially when the mesorectum is short, also make adequate extirpation from below difficult. The length of bowel removed is relatively unimportant in the absence of submucous spread; it is the high division of the mesorectum that really matters. For these additional reasons, it was found that a further *one-sixth* of the cases required a combined excision. Therefore, no less than *two-thirds* of these ano-rectal neoplasms needed treatment by *combined excision*.

Perineal excision was considered adequate in the remaining third. These growths were either small or of moderate size with little or no fixity. There was no evidence of submucous spread and glandular lymphatic deposits were absent in all but a few and then were only slight and limited to the region of the primary growth.

Two-thirds of the malignant neoplasms under review would have brought disappointment to the surgeon who favours perineal excision, whereas he who performs combined excision whenever possible for low-lying rectal carcinomata would seldom regret his choice.

I am grateful to my colleagues at St. Mark's Hospital for their help and for the opportunity to review our more recent cases.

The Surgical Complications of Amœbic Dysentery

By K. L. JAMES, M.S., F.R.C.S.

THE following is an account of my experience of treating surgical complications of amœbic dysentery over a period of three years' service in military hospitals in India. Out of a large intake of cases only a small percentage needed to be transferred to the surgical side.

For a surgeon working in tropical climates the most difficult and anxious problem was the differential diagnosis clinically between acute appendicitis and amœbic infection of the cæcum. It is, however, a most important decision and the same problem is bound to arise in this country following the return of Service personnel from the theatres of war where dysentery is endemic.

The local physical signs in an established case are not very helpful, but Philip Howe states that early in amœbic infection of the cæcum the local signs in the right iliac fossa are already present and predominate over the generalized signs of toxæmia whereas in early acute appendicitis the general signs and referred pains eclipse any physical signs in the right iliac fossa. I regard this as a shrewd observation, and likely to prove helpful when cases are seen early.

Typical cases of acute appendicitis do occur in dysenteric subjects who may still show amœbic cysts if the stools are examined. These are suitable cases for operation and cause no difficulty; nor at the other end of the scale do those patients who are not really suggestive of appendicitis and show entamœbæ in the stools. These must receive medical treatment only. Again, a localized abscess in the right iliac fossa gives rise to no problem since the indication is always for drainage only and there is no question of removing the appendix.

There remain the many difficult cases, and I, personally, place reliance on the following points:

(1) The initial pain of appendicitis is either epigastric or diffuse around the umbilicus; that of amœbiasis of the cæcum is in the right iliac fossa or across the lower part of the abdomen.

(2) Amœbiasis must occur in a previously infected patient and therefore in a patient whose health is below par. Appendicitis, on the other hand, tends to attack a previously healthy subject. Again the history of similar attacks occurring prior to overseas service would rather point to the appendix.

(3) In amœbiasis I found that the tongue was frequently furred in patches and glazed red in other areas, whereas in appendicitis it is uniformly dirty.

My surgical specialists and I all made mistakes and in the early days three soldiers had an appendicectomy performed when the lesion was really amœbic infection of the cæcum. The first progressed satisfactorily with medical treatment. The second died of diffuse faecal peritonitis and the third had the good fortune to form a faecal fistula in the wound from which the contents of the cæcum discharged for eight months.

The truth of the matter is that the amœbic cæcum will not tolerate a purse-string suture nor will the base of such an appendix hold a ligature safely.

After these experiences I instituted in my hospitals the following procedure when a doubtful case of this nature was opened up:

Employing the minimum and most gentle handling of the bowel the surgeon should determine whether the condition of the cæcum was secondary to that of the appendix

Section of Obstetrics and Gynæcology

President—Professor F. J. BROWNE, M.D.

[June 21, 1946]

A Unilateral Krukenberg Tumour with no Apparent Primary Growth.—DOREEN DALEY, M.D., N.R.C.O.G.

A married nulliparous woman, aged 39, seen in January 1945 on account of retrosternal pain of several months' duration, not related to food and worse on bending. Neither physician nor surgeon could find any abnormality and barium swallow and follow through, chest X-ray and E.C.G. were negative.

She was next seen nine months later. Abdominal examination revealed a hard, mobile mass in the right lower abdomen rising from the pelvis almost to the umbilicus. The only associated symptom was three months' amenorrhœa following a regular menstrual cycle. On vaginal examination a normal uterus could be felt separate from the tumour which was diagnosed as a fibroma of the right ovary.

At laparotomy in October 1945 a firm tumour (8 inches across) of the ovary was found on the right side and removed. The surface was smooth and did not show any bosses. Other pelvic organs were normal and there was no ascites. Section of the tumour showed firm almost white tissue with some areas of degenerative breakdown near the hilum. There were no macroscopic hæmorrhages. *Histology*: typical Krukenberg carcinoma.

Further investigation failed to show any primary growth.

Fractional test meal, barium follow-through and enema, tests for occult blood, cholecystography, gastroscopy and sigmoidoscopy all gave negative results.

Progress.—She was given a course of deep X-ray therapy to the pelvic organs and has remained well. X-rays of the spine do not show any abnormality.

When last seen in June 1946 she had put on weight and there was still no evidence of a primary growth nor of enlargement of the other ovary.

Theca-lutein Tumour.—WILLIAM HAWKSWORTH, F.R.C.S.

The pathological specimen and preparations of a theca-cell tumour of the ovary are shown through the courtesy of Dr. Robb-Smith at the Radcliffe Infirmary.

This rare tumour was first described as a separate entity by Löffler and Priesel in 1935. Earlier literature does not appear to contain any descriptions of tumours which correspond in their characteristics to the theca-cell tumour.

Up to 1943 no more than 70 cases had been published.

The theca-cell tumour, or thecoma as it is sometimes called, is a tumour derived from the germinal tissues of the ovary and composed of elements indistinguishable from those that are present in the theca interna under normal physiological conditions of the mature graafian follicle, whether it be in its proliferative or regressive phase.

The tumour commonly occurs in the post-menopausal age-group although cases have been reported which have occurred in the adult reproductive period. It is almost always unilateral and often adherent to neighbouring organs, especially the uterus. In size it may vary from a small nodule in the ovary to a tumour of some 6 in. in diameter. The consistency of the tumour varies according to the proportion between the cellular elements and the fibrous matrix and also varies according to the presence and extent of degenerative changes. The cut surface of the tumour may be of homogeneous structure of yellowish colour, or it may be diffusely mottled with yellow areas separated from one another by whitish or greyish strands of fibrous tissue. Small necrotic areas scattered throughout the solid tumour mass as well as large cysts almost replacing the whole tumour have been described.

Microscopically the picture of the theca-cell tumour is not uniform, and even in the same specimen the cytology and the architecture show different characteristics. Geist and Gaines have given the classical description of the microscopic picture in which they say that the tumour is distinguished especially by "the presence of bundles of bright spindle-shaped cells epithelioid in appearance, distributed in a regular interlacing manner throughout the tumour, and often hyaline plaques". The presence of fat in fairly large amounts within the cells, and to a lesser extent in the surrounding connective tissue, is also stressed. Novak makes a point that in these tumours one does see from time to time areas of cells typical of granulosa cells so that he doubts the advisability of too sharp a definition between granulosa-cell tumours and theca-cell tumours, especially because they have identical endocrine effect. The mingling of epithelium and connective tissue elements in the theca-cell tumour is quite common.

Classically, the cellular elements of the tumour are described in three main groups:
(a) The cell type, which resembles the cellular elements of the theca interna of the

are to be found in the anterior axillary line. In each interspace the needle is inserted in three directions at right angles to the long axis of the body to a depth not exceeding 4 in. It is essential always to use a wide-bored needle (such as is found in the Potain set) if it is hoped to withdraw amœbic pus. Anteriorly aspiration is safe only through the costo-xiphisternal angle.

Open drainage of posterior abscesses was by rib resection with obliteration of the pleural cavity by suture. Anterior abscesses are drained through a high epigastric incision. If the level of the peritoneal reflection has been lowered by the downward enlargement of the liver a tube can be inserted at once. But if drainage is to be transperitoneal then the liver must be stitched to the parietal peritoneum.

It is well known that rupture of a liver abscess into a bronchus is frequently followed by cure but this method of drainage is uncertain and undesirable. It is not too late to aspirate or drain the liver even when the coughing up of blood-stained sputum heralds an imminent rupture.

When an amœbic abscess ruptures into the general peritoneal cavity it is sufficient to insert a suprapubic drain into the pelvis; apparently the slimy amœbic pus does not stimulate the formation of adhesions. Both my cases recovered following this procedure and neither gave rise to any anxiety.

Rupture into the pleural cavity is less fortunate probably for two reasons:

(1) The displacement of the mediastinum. (2) The tendency to diagnose pneumonia with a suspected effusion. The usual chest aspirating needle is not wide enough to withdraw amœbic pus and therefore the true state of affairs is not recognized.

Finally I was greatly impressed by the extreme wasting that occurred in cases of liver abscess. This does not mean a bad prognosis, for however emaciated the patient, his outlook is still hopeful if his abscesses are drained, provided that sufficient liver tissue is left to carry on during the recovery period, and this I find is usually so.

Air Commodore T. C. Morton: In a recent series of over a thousand cases of dysentery invalidated from the tropics, there were ten cases of amœbic liver abscess; spontaneous rupture into the peritoneum occurred in two cases, both of the left lobe of the liver, and in neither case had amœbiasis been suspected prior to laparotomy.

The importance of giving a case of amœbic hepatitis or liver abscess a full course of E.B.I. or some other potent "gut-sterilizing" amœbicide, as a follow-up in convalescence, cannot be too strongly emphasized, as otherwise reinfection from the gut of a previously damaged liver is only too probable. Emetine hydrochloride by needle alone will only cure some 7% of cases of colonic infection. I have seen two cases in the last two years where neglect of this precaution led to a reinfection of the liver, in one case with fatal results, as the second abscess ruptured into a bronchus and eventually a brain abscess developed.

Amœbic stricture of the rectum was only seen in one case for which a colostomy had been carried out in India; the case sheets described a large gangrenous slough of the rectum being passed *per anum* during the routine treatment of the case for amœbiasis. Active *Entamœba histolytica* were reported to have been found on two separate occasions in India and they were found again on his return to the U.K., both from the colostomy opening, and again in biopsy material obtained from the site of the stricture. The probable explanation in this case is that secondary bacterial infection, with a virulent organism, occurred at the site of an amœbic ulcer, leading to an intense localized inflammation which culminated in gangrene. I entirely agree with Sir Philip Manson-Bahr, that a rectal stricture due to *Entamœba histolytica per se* is almost unknown. In four cases of amœbic granuloma (amœboma) of the rectum in which, prior to treatment, it was impossible to attempt to pass a sigmoidoscope beyond the granuloma, complete resolution without diminution of the lumen followed specific emetine and penicillin therapy.

The return of thousands of Service personnel from the tropics to civil life will provide the surgeon with the additional task of excluding amœbiasis in every case of abdominal disorder, and even in hæmorrhoids and anal fistulæ. In doubtful cases I would make a plea for routine sigmoidoscopy in those cases in which the stools are negative for *Entamœba histolytica* cysts, as in 80% of cases of amœbiasis the characteristic crateriform pitting will be found (see Cropper, C. F. J. (1945), Sigmoidoscopy in Amœbic Dysentery, *Lancet* (ii), 460). I have seen an amœbic hepatitis develop following an operation for a proved adenocarcinoma of the colon. On the other hand, six cases of adenocarcinoma of the colon in this series were treated for amœbic dysentery. In two of these the growth was in reach of the examining finger. There is, therefore, a reverse side to the medal and a dual pathology must always be considered in cases of suspected amœbic granuloma refractory to treatment.

Mr. Michael Smyth, M.Ch., read a paper on "Confusion of Amœboma with Carcinoma". see *Lancet*. 1946 (ii). 376.

her own record was good. The menstrual history was normal with a mild degree of dysmenorrhœa.

On examination there were no abnormal physical findings. The adnexæ were apparently healthy and there were no palpable masses. The uterine cavity measured $2\frac{1}{2}$ in. Insufflation of the tubes was successful at a pressure of 180 mm. of mercury but no gas passed when the pressure fell below 120 mm. Biopsy of the endometrium: Secretory in type with some areas of fibrinoid necrosis and a few typical tubercles.

The patient was sent for a chest X-ray, a differential white cell count and E.S.R. before repeating the endometrial biopsy, but only the first of these investigations was carried out as she inadvertently discovered that she was a tuberculous suspect—a suggestion to which she and her husband strongly objected. The chest X-ray was negative.

She remained well until early January 1945, sixteen months later, when she complained of the onset of malaise, fatigue, cold in the head and loss of appetite. The private doctor was in attendance and early in February rigors, headaches, an unproductive cough and the clinical signs of a right-sided pleural effusion made their appearance. The patient was admitted to the Osler Pavilion under the tuberculosis officer on February 18 when she was dyspnoic, and cyanosed. Her menstrual history was still normal. There was no vaginal discharge and no clinical evidence of pelvic pathology but she still complained of a mild degree of dysmenorrhœa.

A week after admission to the sanatorium the patient became irrational, complained of severe headache and pain in the neck. A lumbar puncture revealed 100 lymphocytes per field and a few acid-fast bacilli. The condition slowly deteriorated over the next two weeks and death occurred on March 10.

Post-mortem examination.—The brain and meninges of the cord were studded with tubercles. The right pleural cavity contained an encysted effusion. The external surface of both lungs showed a moderate number of milary tubercles and the cut surfaces showed an early diffuse milary spread. There was no old-standing tuberculous lesion.

The peritoneal cavity was normal and the pelvic organs looked healthy. There were, however, some tags of omentum adherent to the posterior surface of the uterus. It was not clear whether this was an old process or a response to the recent milary spread. The fallopian tubes and endometrium showed no abnormality nor thickening; in fact the tubes were perhaps smaller in diameter than normal. The kidneys showed an occasional milary tubercle on their cut surfaces. In the mesentery at the lower end of the small intestine there was one calcified lymph node 1 cm. in diameter with several smaller hard fibrotic lymph nodes in relation to it. Microscopically there were tubercles in the fallopian tubes and endometrium although to the naked eye these appeared normal. Diffuse milary tubercles were also found in the liver, lungs, pleuræ and meninges.

The conclusions arrived at were that the original infection was the mesenteric lymph node, then the endometrium and finally a blood-stream dissemination.

During the last four years I have collected 17 cases of endometrial biopsies revealing tuberculous endometritis with no other clinically recognizable affection of the pelvic organs, and in no other case has there developed a spread of the tuberculous process beyond the pelvis, nor has any proved fatal. But on the other hand, no treatment has been successful in curing the tuberculous endometrium and in some cases, the spread to the adjacent pelvic viscera has called for surgical interference, and an operation for total hysterectomy and bilateral oophorectomy has been performed. Whilst in others, no treatment whatsoever has been given and no symptoms have arisen and there have been no unfavourable results to the general health.

Double Uterus and Bilateral Pyosalpinx.—ELIZABETH M. ROSE, M.B.

The specimen demonstrated was obtained at operation from a patient who gave the following history. In August 1938 when aged 23 and unmarried she was admitted to hospital complaining of severe pain in the R.I.F. for the first three days of menstrual periods. This had been recurring for four years and had not been relieved by appendicectomy. She was examined under anaesthesia and dilatation and curettage were carried out but no abnormality was found. Seven months later she reported again, now married and three months' pregnant, complaining of slight irregular vaginal bleeding and constant pain in the R.I.F. On vaginal examination a mass was felt to the left of the pregnant uterus. Laparotomy was performed and a double uterus was found with a pregnancy in the right horn. In the course of investigations an intravenous pyelogram revealed only one kidney and ureter which were on the left side. The pregnancy continued and was normal apart from the pain which persisted until the fifth month. The pain in the R.I.F. during menstruation was less severe after the pregnancy, but it returned and persisted, again for almost five months, when she became pregnant for the second time in 1944. Delivery and puerperium were normal as before.

More than a year later, in January 1946, she reported to hospital again. She had been completely free from pain until five weeks previously, since when it had been severe

maturing graafian follicle where the cells are slender, spindle-shaped, with well-developed fibrous projections, elongated, deeply-staining nuclei and scanty protoplasm containing minute lipid droplets, or (b) cells similar to the theca interna as they appear immediately prior to rupture of the follicle, that is, ovoid or plump cells with deeply-staining atrophic fibrillary processes, roundish or ovoid nuclei and abundant fat-laden protoplasm, or (c) those cells which resemble the theca-cells after the rupture of the follicle, i.e. theca-lutein cells; these cells are polyhedral in shape, show no evidence of fibrillary projections under the usual staining methods, have central nuclei and abundant lipid in the protoplasm.

The lipid is, of course, well brought out by the usual methods of staining frozen sections of the tumour with Sudan 3 or 4, the intra-cellular lipid then appearing as bright red droplets.

The fibrous matrix of the tumour sometimes shows a picture of definite connective tissue type, alternating with areas with lack of regular arrangement. The fibroblasts are usually arranged in regular bundles and, as has already been stated, the cells of the tumour may be arranged in bundles or irregularly scattered through the matrix. The actual matrix itself is made up by fibrous projections of the cells themselves, as well as the fibroblasts. Occasionally these projections may show hyalinization.

The proportion of the cellular elements to the fibrous matrix varies considerably. The fibrous tissue gives the whitish or greyish appearance to the tissue strands in the tumour, and the fat-laden cells of the cellular elements macroscopically give the yellow colour to the tumour.

Briefly, the histogenesis of the tumour is probably best considered as arising from remnants of early mesenchymal cells, as postulated particularly by Novak and Barzilai. The symptomatology of this tumour is due, as is widely known, to the fact that it produces the female sex hormone which is responsible for changes in the endometrium, myometrium and the breast, similar to those observed in cases of granulosa-cell tumour. As a result, in post-menopausal women an irregular bleeding is the outstanding feature. During the reproductive phase, the irregularity is characterized by periods of amenorrhoea and followed by recurrent irregular periods of bleeding. All these manifestations disappear following removal of the tumour. In the differential diagnosis, owing to the fact that these tumours have been adherent to the uterus, they are frequently mistaken for fibromyomata. As a rule, this tumour is benign, but examples of proven malignancy have been described. In their treatment removal of the tumour is adequate, except in cases of malignancy where a pan-hysterectomy should be performed and followed by deep X-ray therapy.

The tumour under discussion was removed at operation from a patient aged 62, who came to hospital complaining of a blood-stained discharge for the past two months. At operation, a dilatation and curettage was performed to exclude carcinoma of the body of the uterus, and hypertrophied endometrium, characteristic of metropathia was obtained, and this, in association with a palpable small left ovarian tumour, suggested the diagnosis of a granulosa-cell tumour. The uterus and tumour were removed vaginally by Mr. Stallworthy, and the patient has made an uninterrupted recovery.

The specimen shows a left ovary enlarged to $5\frac{1}{2}$ cm. in diameter and the right ovary atrophic and normal in size for a patient of this age. The cut surface of the tumour shows little nodular patches of yellow tissue separated by strands of white or greyish fibrous connective tissue. The yellowish colour was more pronounced prior to the mounting of the specimen, but it is still sufficiently well marked to be seen without difficulty.

The endometrium appeared to be slightly thickened and the myometrium did not show any macroscopic hyperplasia. Microscopic slides show the characteristic architecture of a theca-cell tumour. The cells are varied, some spindle-shaped, others ovoid, rather plump, with roundish or ovoid nuclei and with fibrous tissue elements making up the matrix of the tumour. These are well shown in the slides stained by Masson's trichrome, and in some areas this fibrous tissue is thicker than others and gives a hyaline appearance. The cells themselves tend to scatter and extend from the epithelial masses in amongst the surrounding connective tissue. The staining does not show particularly well the fibrillary projections from the individual cells which help to make up the matrix.

This case is one of an ovarian neoplasm occurring in a patient after the menopause and giving rise to post-menopausal bleeding. The microscopical picture resembles theca interna of a physiological graafian follicle prior to ovulation, and hence the name theca-cell tumour.

Tuberculous Endometritis with Miliary Spread.—M. KATHLEEN LAWLOR, F.R.C.S.Ed.

Married woman, aged 40, attended the sterility clinic at the Radcliffe Infirmary in August 1943. She had been married five years, and had been desirous of becoming pregnant for the previous three years. Her husband, 36 years of age, was healthy and

her own record was good. The menstrual history was normal with a mild degree of dysmenorrhœa.

On examination there were no abnormal physical findings. The adnexæ were apparently healthy and there were no palpable masses. The uterine cavity measured $2\frac{1}{2}$ in. Insufflation of the tubes was successful at a pressure of 180 mm. of mercury but no gas passed when the pressure fell below 120 mm. Biopsy of the endometrium: Secretory in type with some areas of fibrinoid necrosis and a few typical tubercles.

The patient was sent for a chest X-ray, a differential white cell count and E.S.R. before repeating the endometrial biopsy, but only the first of these investigations was carried out as she inadvertently discovered that she was a tuberculous suspect—a suggestion to which she and her husband strongly objected. The chest X-ray was negative.

She remained well until early January 1945, sixteen months later, when she complained of the onset of malaise, fatigue, cold in the head and loss of appetite. The private doctor was in attendance and early in February rigors, headaches, an unproductive cough and the clinical signs of a right-sided pleural effusion made their appearance. The patient was admitted to the Osler Pavilion under the tuberculosis officer on February 18 when she was dyspnoeic, and cyanosed. Her menstrual history was still normal. There was no vaginal discharge and no clinical evidence of pelvic pathology but she still complained of a mild degree of dysmenorrhœa.

A week after admission to the sanatorium the patient became irrational, complained of severe headache and pain in the neck. A lumbar puncture revealed 100 lymphocytes per field and a few acid-fast bacilli. The condition slowly deteriorated over the next two weeks and death occurred on March 10.

Post-mortem examination.—The brain and meninges of the cord were studded with tubercles. The right pleural cavity contained an encysted effusion. The external surface of both lungs showed a moderate number of milary tubercles and the cut surfaces showed an early diffuse milary spread. There was no old-standing tuberculous lesion.

The peritoneal cavity was normal and the pelvic organs looked healthy. There were, however, some tags of omentum adherent to the posterior surface of the uterus. It was not clear whether this was an old process or a response to the recent milary spread. The fallopian tubes and endometrium showed no abnormality nor thickening; in fact the tubes were perhaps smaller in diameter than normal. The kidneys showed an occasional milary tubercle on their cut surfaces. In the mesentery at the lower end of the small intestine there was one calcified lymph node 1 cm. in diameter with several smaller hard fibrotic lymph nodes in relation to it. Microscopically there were tubercles in the fallopian tubes and endometrium although to the naked eye these appeared normal. Diffuse milary tubercles were also found in the liver, lungs, pleuræ and meninges.

The conclusions arrived at were that the original infection was the mesenteric lymph node, then the endometrium and finally a blood-stream dissemination.

During the last four years I have collected 17 cases of endometrial biopsies revealing tuberculous endometritis with no other clinically recognizable affection of the pelvic organs, and in no other case has there developed a spread of the tuberculous process beyond the pelvis, nor has any proved fatal. But on the other hand, no treatment has been successful in curing the tuberculous endometrium and in some cases, the spread to the adjacent pelvic viscera has called for surgical interference, and an operation for total hysterectomy and bilateral oophorectomy has been performed. Whilst in others, no treatment whatsoever has been given and no symptoms have arisen and there have been no unfavourable results to the general health.

Double Uterus and Bilateral Pyosalpinx.—ELIZABETH M. ROSE, M.B.

The specimen demonstrated was obtained at operation from a patient who gave the following history. In August 1938 when aged 23 and unmarried she was admitted to hospital complaining of severe pain in the R.I.F. for the first three days of menstrual periods. This had been recurring for four years and had not been relieved by appendicectomy. She was examined under anaesthesia and dilatation and curettage were carried out but no abnormality was found. Seven months later she reported again, now married and three months' pregnant, complaining of slight irregular vaginal bleeding and constant pain in the R.I.F. On vaginal examination a mass was felt to the left of the pregnant uterus. Laparotomy was performed and a double uterus was found with a pregnancy in the right horn. In the course of investigations an intravenous pyelogram revealed only one kidney and ureter which were on the left side. The pregnancy continued and was normal apart from the pain which persisted until the fifth month. The pain in the R.I.F. during menstruation was less severe after the pregnancy, but it returned and persisted, again for almost five months, when she became pregnant for the second time in 1944. Delivery and puerperium were normal as before.

More than a year later, in January 1946, she reported to hospital again. She had been completely free from pain until five weeks previously, since when it had been severe

and constant in the same position as before. It was associated with a yellow vaginal discharge and irregular severe bleeding. On examination she was slightly febrile, T. 99·8, P. 88, and she did not look acutely ill though she was debilitated. There was tenderness in both iliac fossæ, most marked on the right side. On vaginal examination two masses could be felt, that on the left appeared to be a normal uterus while that on the right was round, firm and tender. There was slight tenderness in the left fornix. As it was considered possible that there might be a tubal pregnancy the abdomen was opened and bilateral pyosalpinx was found with the double uterus which had a single cervix. Small bowel was lightly adherent to the right tube but was separated easily, and bilateral salpingo-oophorectomy and total hysterectomy were carried out. The unilateral ureter did not cause any difficulty and the patient made a good recovery.

The case illustrates several practical points which may arise in patients with double uterus. Frequently they complain of disordered menstruation which may be irregular or painful. The condition is most often diagnosed during pregnancy, however, when the abdomen may be opened, as in this case, to exclude ovarian cyst or ectopic gestation. It is relatively common to find developmental abnormalities of the renal and genital tracts occurring in the same patient and one must bear this in mind when operating on any woman with double uterus. Another difficulty less well appreciated is that the knowledge that a patient has a double uterus may confuse the diagnosis of superimposed pelvic disease.

This patient was fortunate in having no difficulty when in labour. Commonly premature labour occurs or inertia, or the non-pregnant horn may obstruct delivery. Malpresentation, post-partum hæmorrhage and retained placenta are frequent. Perhaps the most common symptom of double uterus is habitual abortion. A patient was described who had had four early miscarriages and no normal pregnancies. On each of the last three occasions she was told that there was a tumour complicating the pregnancy. Each time she reported for treatment of the tumour after recovering from the miscarriage, but when she was not pregnant the mass could not be felt. At last she was investigated by hystero-salpingogram which explained the phantom tumour. The X-ray demonstrated clearly the same abnormality as we found in the previous case—a uterus bicornu is unicollis.

Eclampsia on the 26th Day After Delivery.—W. R. WINTERTON, F.R.C.S.

Mrs. M. D., aged 28, primigravida, was due on April 29, 1946. Pregnancy was normal, except for some giddy attacks in February. She was Rh-positive.

Three weeks before she was due she developed some œdema of the ankles but there was no albumin in the urine and the blood-pressure was 120/80. The head was engaged. She went into labour on May 2. Labour was prolonged and lasted four days, ending with a low forceps delivery. The third stage was normal.

During the puerperium her temperature remained between 99° and 100° and her pulse was rapid. On the ninth day she had a secondary post-partum hæmorrhage of fifteen ounces. She was curetted and some offensive blood clot was removed. There were no placental remains. Following the curettage she complained of headaches. On the sixteenth day some œdema of her legs was noticed. Her blood-pressure was then 120/70.

On the seventeenth day she had another slight loss. She was given a blood transfusion, but later in the day she had another post-partum hæmorrhage. Another curettage was performed but again no placental remains were removed. She was given another transfusion of two pints of blood. From then on the œdema became more marked and generalized. The œdema of the conjunctivæ was particularly noticeable and the urinary output began to drop to about fifteen ounces daily.

On May 31, the twenty-sixth day after delivery, she had a fit. During the course of the day she had eight fits. Her blood-pressure was 190/150 and the urine boiled solid. The output could not be measured as she was incontinent, but it was very small.

She was treated with sedatives and later that night when she appeared moribund was given a high spinal anaesthetic, double strength plasma and ten ounces of 5% sodium sulphate intravenously. Twelve hours later she began to regain consciousness, complained of thirst and passed thirty ounces of urine.

For the next three days she was drowsy and incontinent and the blood-pressure remained about 170/110. She then rapidly improved and by the tenth day after the fits her blood-pressure had returned to 140/90. She returned home on June 19.

On the day of the fits her blood urea was 43 mg. per 100 ml. The urine showed red cells but no leucocytes or casts.

When seen two months later, she was very well, the blood-pressure was 140/70 and there was no albumin in the urine.

Mr. Everard Williams showed a specimen of carcinoma of the cervix treated by removal of uterus and bladder in continuity after preliminary ureteric transplantation.

Section of Radiology

President—W. M. LEVITT, M.D., F.R.C.P.

[May 17, 1946]

DISCUSSION ON THE PLACE OF THE RADIOLOGIST IN THE NATIONAL HEALTH SERVICE

Dr. S. Cochrane Shanks: In considering the title of this Discussion: "The Place of the Radiologist in the National Health Service", I am at once in a difficulty, that of definition. To me the term radiologist conjures the picture of one who attempts X-ray diagnosis. To many others he is one who attempts the cure of cancer with X-rays.

Let me begin by claiming for radiologists a finger in as many pies as possible; not only in the hospital, where our place is assured, but elsewhere also: the Central Health Service Council, the Regional Hospital Board, and the Health Centre with an X-ray department.

The Central Health Service Council.—This body is to consist of 41 members, 21 of them medical. Of the latter, 6 are *ex officio*—the Presidents of the three Royal Colleges and of the G.M.C., the Chairman of the Council of the B.M.A. and of the Society of Medical Officers of Health, and two allocated to the mental services. This leaves 13 places for the representatives of the general practitioner and consultant services. Not very many—but I think we should press very strongly for at least one of these on the grounds of the importance of our specialty to all other branches, and the magnitude of our work in hospitals. Failing that, we should certainly have one representative of each of the sections of radiology on the Standing Medical Committee of the Central Council.

The Regional Hospitals Board.—The Minister has stated that the personnel of the Regional Hospitals Board will be chosen for their knowledge and administrative ability on hospital matters, and while he will seek the advice of the local authorities, the medical profession, the universities and others, the members chosen will not be sectional representatives, and so whether a radiologist is chosen or not as a member will depend on whether he has the above qualities, irrespective of his specialty. There would be no certainty, therefore, that a radiologist would be a member of the Board. In order to provide any technical advice that the Board might require, there should be appointed in each region an adviser in radiology, assisted maybe by a committee elected by the radiologists of the region. Such an adviser or committee would exercise a number of useful functions, such as having a voice on the University Appointments Committee of the region when radiological appointments were under consideration.

Again, if, as I suspect, the bulk ordering of major X-ray equipment is to be a matter for the Regional Hospital Board, who better could advise on this than a committee of radiologists of the region? I earnestly hope that the individual hospital radiologist will be given a very free choice of apparatus to suit his individual requirements, but bulk ordering will be economically attractive, and the advice of such a committee would ensure a sufficient variety in the bulk ordering to suit individual preference.

Status of the radiologist in hospitals.—There can be no doubt of the importance of the X-ray departments in hospitals: the diagnostic department deals with cases from every other department in the hospital and persistently doubles its numbers—and costs—every few years; while the radiotherapy departments become larger, more efficient and certainly fewer in number with every pronouncement of the Faculty of Radiologists.

and constant in the same position as before. It was associated with a yellow vaginal discharge and irregular severe bleeding. On examination she was slightly febrile, T. 99.8, P. 88, and she did not look acutely ill though she was debilitated. There was tenderness in both iliac fossæ, most marked on the right side. On vaginal examination two masses could be felt, that on the left appeared to be a normal uterus while that on the right was round, firm and tender. There was slight tenderness in the left fornix. As it was considered possible that there might be a tubal pregnancy the abdomen was opened and bilateral pyosalpinx was found with the double uterus which had a single cervix. Small bowel was lightly adherent to the right tube but was separated easily, and bilateral salpingo-oophorectomy and total hysterectomy were carried out. The unilateral ureter did not cause any difficulty and the patient made a good recovery.

The case illustrates several practical points which may arise in patients with double uterus. Frequently they complain of disordered menstruation which may be irregular or painful. The condition is most often diagnosed during pregnancy, however, when the abdomen may be opened, as in this case, to exclude ovarian cyst or ectopic gestation. It is relatively common to find developmental abnormalities of the renal and genital tracts occurring in the same patient and one must bear this in mind when operating on any woman with double uterus. Another difficulty less well appreciated is that the knowledge that a patient has a double uterus may confuse the diagnosis of superimposed pelvic disease.

This patient was fortunate in having no difficulty when in labour. Commonly premature labour occurs or inertia, or the non-pregnant horn may obstruct delivery. Malpresentation, post-partum hæmorrhage and retained placenta are frequent. Perhaps the most common symptom of double uterus is habitual abortion. A patient was described who had had four early miscarriages and no normal pregnancies. On each of the last three occasions she was told that there was a tumour complicating the pregnancy. Each time she reported for treatment of the tumour after recovering from the miscarriage, but when she was not pregnant the mass could not be felt. At last she was investigated by hystero-salpingogram which explained the phantom tumour. The X-ray demonstrated clearly the same abnormality as we found in the previous case—a uterus bicornis unicollis.

Eclampsia on the 26th Day After Delivery.—W. R. WINTERTON, F.R.C.S.

Mrs. M. D., aged 28, primigravida, was due on April 29, 1946. Pregnancy was normal, except for some giddy attacks in February. She was Rh-positive.

Three weeks before she was due she developed some œdema of the ankles but there was no albumin in the urine and the blood-pressure was 120/80. The head was engaged. She went into labour on May 2. Labour was prolonged and lasted four days, ending with a low forceps delivery. The third stage was normal.

During the puerperium her temperature remained between 99° and 100° and her pulse was rapid. On the ninth day she had a secondary post-partum hæmorrhage of fifteen ounces. She was curetted and some offensive blood clot was removed. There were no placental remains. Following the curettage she complained of headaches. On the sixteenth day some œdema of her legs was noticed. Her blood-pressure was then 120/70.

On the seventeenth day she had another slight loss. She was given a blood transfusion, but later in the day she had another post-partum hæmorrhage. Another curettage was performed but again no placental remains were removed. She was given another transfusion of two pints of blood. From then on the œdema became more marked and generalized. The œdema of the conjunctivæ was particularly noticeable and the urinary output began to drop to about fifteen ounces daily.

On May 31, the twenty-sixth day after delivery, she had a fit. During the course of the day she had eight fits. Her blood-pressure was 190/150 and the urine boiled solid. The output could not be measured as she was incontinent, but it was very small.

She was treated with sedatives and later that night when she appeared moribund was given a high spinal anæsthetic, double strength plasma and ten ounces of 5% sodium sulphate intravenously. Twelve hours later she began to regain consciousness, complained of thirst and passed thirty ounces of urine.

For the next three days she was drowsy and incontinent and the blood-pressure remained about 170/110. She then rapidly improved and by the tenth day after the fits her blood-pressure had returned to 140/90. She returned home on June 19.

On the day of the fits her blood urea was 43 mg. per 100 ml. The urine showed red cells but no leucocytes or casts.

When seen two months later, she was very well, the blood-pressure was 140/70 and there was no albumin in the urine.

Mr. Everard Williams showed a specimen of carcinoma of the cervix treated by removal of uterus and bladder in continuity after preliminary ureteric transplantation.

the radiotherapy department as an out-patient, for he will be entitled to treatment free of charge under the scheme. The differentiation in out-patients might be clearer if free treatment under the scheme was permissible only on reference from the out-patient clinics of the hospital—i.e. if the department were a "closed" one, except to private out-patients.

The case of the X-ray diagnostician is even more complicated, for so much of his work is on out-patients. Many of us are, at present, in private practice and can arrange to see our private cases—if not bedfast—in our private rooms. But in future, with the inevitable diminution in private work, and with the mounting costs of X-ray installations, few radiologists will care to face the expense of establishing private consulting rooms, and the majority will be driven to doing their private work in their hospitals. Again, the presence in the hospitals of private wards, and the principle of the open or closed department will be the deciding factors in the maintenance of private X-ray diagnostic practice.

In favour of the closed department in respect of the Comprehensive Service it is said that otherwise the departments may be flooded with unnecessary work. If everything is "free on the house" one can picture the request for a barium meal and follow through, and a barium enema; if nothing is found a cholecystography, and possibly an I.V.P. thrown in on the chance. If a patient has to pay for all that he will think twice. If it is free, the onus is thrown on the radiologist to refuse the unnecessary examination.

A more pertinent objection to the open department is in the teaching hospital, since valuable clinical material might be lost to the out-patient teaching clinics by the short circuit.

Those who favour the open department say, with considerable reason, that the family doctor is capable of handling the clinical aspect of many a case himself, and that the patient should not be forced to run the gauntlet of the out-patient clinic merely to obtain radiological evidence. In this respect, there is the recent recommendation of the Annual Representative Meeting of the British Medical Association, passed by an overwhelming majority, that general practitioners should have direct access for their patients to X-ray and pathological services, without the intervention of hospital clinicians. In some cases this may be available in health centres and cottage hospitals staffed by general practitioners, but there is no doubt that it will also be demanded in district hospitals and probably also in teaching hospitals.

Control of X-ray departments.—I should like now to insist on the principle that the radiologist should have effective charge of all the X-ray services in the institution. I have in mind a growing tendency in diagnostic departments to nuclear fission, particularly under the impact of orthopaedic neutrons. This disruption by the orthopaedists is sometimes difficult to resist, since, if their fracture clinics are situate some distance from the X-ray department, their demand for a subsidiary X-ray unit in the fracture department is very reasonable.

When they tell us that they want to have a picture of a fracture taken while the patient is under an anaesthetic, to view the pictures, and if necessary further to correct the displacement, all before the patient recovers consciousness, they are on very sure ground. The patient is entitled to that service, and we must give it, even if it means installing a unit and dark-room in the fracture clinic. But I see no objection to this arrangement if we insist tenaciously on two things: first that the subsidiary unit and the radiographer working it are part of the main department, and under the direction and control of the radiologist, and secondly, and most importantly, that every film taken in the subsidiary unit is seen and reported on by the radiological staff. It will often be after the event—it may be the next day—but this procedure gives the radiologist the opportunity of checking day by day the X-ray work done in the subsidiary department, and of drawing attention to any point in the X-ray aspect of a case missed by the clinicians, before harm is done.

Academic posts in radiology.—The establishment of university posts in any specialty should relate to the amount of teaching undertaken. Now it is true that radiologists are called upon to undertake little systematized undergraduate teaching. This is, I think, right and proper, for there is little room in the overcrowded undergraduate curriculum for systematized detailed teaching of radiology by radiologists. That in the main must be done by the clinicians at the bedside and in out-patient clinics. There is certainly not enough to warrant on those grounds alone the appointment of a university professor or reader. But, when we consider the increasing demands of post-graduate teaching, the story is very different. In London there are this year about 100 post-graduate students training for a diploma in radiology. Even if this is a peak year, there will be, I feel sure, a large number of students presenting themselves in years to come to meet the

Radiologists should, therefore, rank equally with their colleagues on the consultant staff of the hospital, with the right to sit on the medical committee, eligible to serve on the committee of management of the hospital, and to take a part in the management of our medical schools.

Organization of a radiotherapy department.—Radiotherapy of malignant disease should be conducted only in large, well-equipped and staffed centres which will tend to be in the university hospitals. In the provinces the problem is simpler than in London, where there are 12 teaching hospitals. In each of these there *must* be a major cancer centre, in order that the undergraduate students—the doctors of the future who will be responsible for the early diagnosis of cancer—may see a sufficiency of cancer cases, in the wards and out-patient clinics.

If radiotherapy has to be sent to another institution, the cancer cases will inevitably gravitate to where all the services are available. I suggest that some compromise is necessary in London by establishing a radiotherapy centre in each teaching hospital, linked together in some cases, maybe, for staffing, research and record purposes.

Organization of X-ray diagnostic departments.—There can be few working in hospital departments who are not concerned at the difficulty in keeping abreast of the ever-increasing stream of patients that pour into these departments. No sooner does one, by extension of accommodation, equipment or staff, obtain a little breathing space, than fresh increases, fresh demands threaten to engulf the department again.

Owing to the ever-increasing demands on hospitals it is seldom that the standard of work in even the good departments equals that turned out by the best of those in private practice, even if the same man be in charge of both. The remedy is clear: a sufficient number of properly trained radiologists should be employed to ensure that every case is seen by the radiologist on arrival in the department. A history should be taken, precise instructions given to the radiographer, and all films should be seen and passed by the radiologist before the departure of the patient. Then, and then only, will the quality of the work be of the highest grade.

Training of radiologists.—The criteria laid down for consultants by the Joint Committee of the Royal Colleges should apply to radiologists as to other specialists. In the initial stages of the Health Service there will be but one yardstick, the recognition by his peers that a man is a *de facto* consultant. For the future more will be necessary. One or more house appointments in medicine or surgery, a diploma course culminating in a diploma, preceded or succeeded, maybe, by taking a higher medical, surgical or radiological qualification. Finally—and here is the essence—at least three years' training as a junior in a big X-ray department, diagnostic or therapeutic. This is the only way in which to develop a first-class X-ray service for the country; and during most of his training the aspirant will be earning a reasonable living. And here may I point out a gap in our X-ray diagnostic training, in the art of radiography itself. Most of us who are established, can claim considerable experience in practical radiography in our private practice. In future, when most radiographic work is done by technicians in hospitals, there is a danger of a generation of radiologists growing up who neither position the patient nor push an exposure button. We must, therefore, plan our system of training to include for our trainees some formal and deliberate duty as radiographers in our departments.

Encouragement in research work.—As soon as our juniors have attained enough experience, they should be encouraged to undertake some work of investigation or research. The ever-increasing burden of routine work in hospital and private practice has stifled the urge to research, and denied the time for it. All this will, I hope, be changed, but only by planning the Service and training enough personnel to give leisure for this all-important aspect of our work.

Terms of service of radiologists.—Salary scales will be settled generally for all consultants: but it is appropriate to discuss whether we are to be employed part-time in hospital and part-time in private practice outside the hospital, or whole-time in one or more hospitals; and if the latter, whether we shall be allowed to see private patients in our hospitals.

To take the simpler problem first, that of radiotherapists. There seems little doubt that radiotherapy for malignant disease will in future be conducted in the main in properly organized hospital centres, and that, therefore, radiotherapists will be employed whole-time in institutions. Where his colleagues are allowed private practice in the hospital, it seems only fair that radiotherapists should have the like privilege, even if there be no segregated private section of the radiotherapy department. There may be some administrative difficulty—in deciding which patients should pay a fee. The differentiation is clear where the patient is an in-patient in the private wing, but not so clear if he attends

the radiotherapy department as an out-patient, for he will be entitled to treatment free of charge under the scheme. The differentiation in out-patients might be clearer if free treatment under the scheme was permissible only on reference from the out-patient clinics of the hospital—i.e. if the department were a "closed" one, except to private out-patients.

The case of the X-ray diagnostician is even more complicated, for so much of his work is on out-patients. Many of us are, at present, in private practice and can arrange to see our private cases—if not bedfast—in our private rooms. But in future, with the inevitable diminution in private work, and with the mounting costs of X-ray installations, few radiologists will care to face the expense of establishing private consulting rooms, and the majority will be driven to doing their private work in their hospitals. Again, the presence in the hospitals of private wards, and the principle of the open or closed department will be the deciding factors in the maintenance of private X-ray diagnostic practice.

In favour of the closed department in respect of the Comprehensive Service it is said that otherwise the departments may be flooded with unnecessary work. If everything is "free on the house" one can picture the request for a barium meal and follow through, and a barium enema; if nothing is found a cholecystography, and possibly an I.V.P. thrown in on the chance. If a patient has to pay for all that he will think twice. If it is free, the onus is thrown on the radiologist to refuse the unnecessary examination.

A more pertinent objection to the open department is in the teaching hospital, since valuable clinical material might be lost to the out-patient teaching clinics by the short circuit.

Those who favour the open department say, with considerable reason, that the family doctor is capable of handling the clinical aspect of many a case himself, and that the patient should not be forced to run the gauntlet of the out-patient clinic merely to obtain radiological evidence. In this respect, there is the recent recommendation of the Annual Representative Meeting of the British Medical Association, passed by an overwhelming majority, that general practitioners should have direct access for their patients to X-ray and pathological services, without the intervention of hospital clinicians. In some cases this may be available in health centres and cottage hospitals staffed by general practitioners, but there is no doubt that it will also be demanded in district hospitals and probably also in teaching hospitals.

Control of X-ray departments.—I should like now to insist on the principle that the radiologist should have effective charge of all the X-ray services in the institution. I have in mind a growing tendency in diagnostic departments to nuclear fission, particularly under the impact of orthopaedic neutrons. This disruption by the orthopaedists is sometimes difficult to resist, since, if their fracture clinics are situate some distance from the X-ray department, their demand for a subsidiary X-ray unit in the fracture department is very reasonable.

When they tell us that they want to have a picture of a fracture taken while the patient is under an anaesthetic, to view the pictures, and if necessary further to correct the displacement, all before the patient recovers consciousness, they are on very sure ground. The patient is entitled to that service, and we must give it, even if it means installing a unit and dark-room in the fracture clinic. But I see no objection to this arrangement if we insist tenaciously on two things: first that the subsidiary unit and the radiographer working it are part of the main department, and under the direction and control of the radiologist, and secondly, and most importantly, that every film taken in the subsidiary unit is seen and reported on by the radiological staff. It will often be after the event—it may be the next day—but this procedure gives the radiologist the opportunity of checking day by day the X-ray work done in the subsidiary department, and of drawing attention to any point in the X-ray aspect of a case missed by the clinicians, before harm is done.

Academic posts in radiology.—The establishment of university posts in any specialty should relate to the amount of teaching undertaken. Now it is true that radiologists are called upon to undertake little systematized undergraduate teaching. This is, I think, right and proper, for there is little room in the overcrowded undergraduate curriculum for systematized detailed teaching of radiology by radiologists. That in the main must be done by the clinicians at the bedside and in out-patient clinics. There is certainly not enough to warrant on those grounds alone the appointment of a university professor or reader. But, when we consider the increasing demands of post-graduate teaching, the story is very different. In London there are this year about 100 post-graduate students training for a diploma in radiology. Even if this is a peak year, there will be, I feel sure, a large number of students presenting themselves in years to come to meet the

increasing requirements of the X-ray service of the future. London University has a Professor of Radiotherapy but none in X-ray Diagnosis, and there is urgent need for at least one such of the latter in London. Indeed, two chairs in each branch of the specialty would be a great advantage from the point of view of post-graduate teaching. It is not only in London that professorships are desirable. They should be established in every university centre in the kingdom where systematized post-graduate instruction is being carried out, or where it might usefully be carried out in future.

Distribution of radiologists in the service.—I have touched on the administrative, hospital and academic status of radiologists, and on the types of appointments that radiologists might expect to hold in the future. Finally, we might also usefully consider the pattern of distribution of radiologists not only in university teaching and district hospitals, but also cottage hospitals and health centres, tuberculosis clinics and mass radiography units. Our help will also be required for domiciliary X-ray services in the patients' homes, and I hope in dermatological X-ray therapy units, working in collaboration with the dermatologist.

The diagram below indicates the broad pattern of hospital organization that will probably be adopted in the region. The university teaching hospital, with its medical school,

DISTRIBUTION OF RADIOLOGISTS IN A REGION.

If the teaching hospital acts also as a district hospital, it too should link to the ancillary services as above.

will be the academic centre and, it is hoped, the principal inspirational centre for the profession in the region. It will take its part in the regional hospital service in so far as its educational pre-occupations permit. But the backbone of the hospital service will be the district hospital centre—either one hospital or a group of linked hospitals of the district or division, with a bed accommodation of about 1,000. It has been suggested that this district centre should serve a population, on the average, of 150,000 and that there may be 10 to 20 districts or divisions in each region. To the centre should be linked the ancillary institutions as indicated in the diagram.

I have stated the thesis that X-ray diagnostic work can reach its maximum efficiency only if there is a radiologist constantly present during working hours to give personal detailed supervision to every case, and we must so design the distribution of radiologists that this requirement is met, even in small institutions where there is not enough work for a whole-time radiologist. The ideal would be to centre the radiological service of each area of the region in the district hospital (or hospitals) serving that area, in such a way that all the radiologists of the area are attached to that hospital in some capacity or other; and at this stage in the organization I think there is room for some directional control of the radiological service. There should be a director, preferably whole-time, responsible for organization of the whole X-ray service of the district. At least one senior, the X-ray director of the district, should be whole-time in the district centre—the others serving part-time in the district hospital and part-time in one or more of the ancillary institutions. The advantages of such a grouping are obvious: the benefit to all of professional contact and exchange of views and experience, the opportunity so afforded for members of the team to specialize in various branches of our work, and the avoidance of the temptation to undertake in the smaller institutions investigations or therapeutic measures which require the larger facilities of the central hospital.

The Consultant Services Committee and the Faculty of Radiologists have estimated the number of radiologists required for this service at 12 to 16 per million of the population. Recent discussions indicate that this figure may be much too low, and that more than double that number may be necessary to give the necessary detailed individual attention to X-ray work. If that should prove to be true, upwards of 2,000 radiologists may be necessary to implement the service of the future. It will obviously take many

years to train such numbers, and it must be regarded as a long-term policy, impossible to achieve with hospitals and staffs as they are. But if we are going to build a brave new hospital world let our part of it be designed with courage and vision, with proper accommodation and equipment, adequate professional and subordinate staff, real opportunity for consultation on the problems that face us, leisure for thought and for research, and, above all, freedom to investigate and treat our patients *secundum artem* trammelled only by the constructive help and criticism of our compeers.

Dr. Richard Fawcitt [Abridged]: The voluntary hospitals in England and Wales, 1,059 in number, provide 93,000 beds, of these one-third consist of hospitals with fewer than 100 beds.

The municipal hospitals provide 152,000 beds—78,000 of which are for general purposes, i.e. excluding infectious diseases, &c.; of these 78,000 beds 29,000 are in Public Assistance Institutions providing food and shelter for the clinically infirm and aged (see *Brit. med. J.*, 1946 (i), 653).

Numerically the non-teaching hospitals far exceed the teaching hospitals.

It is with these non-teaching hospitals that I am concerned in my remarks to-day.

It is not my purpose to deal with the past, though the present is unfortunately in many cases bound up with the past—particularly as far as accommodation is concerned—still many X-ray departments are hampered by lack of cubic space, ventilation, daylight, insufficient apparatus due to lack of room, and darkrooms little better than a cupboard.

Now as to the present. I thought it advantageous to send out a questionnaire to a colleague in each county in England and ask for his observations, preference being given to men serving more than one type of hospital, but not so in every case—I did not personally choose the individuals to whom the questionnaire was sent. The selection was made from the County Hospital list of the 1945 Medical Directory. When checking up these items in the Directory several interesting facts appeared: (1) That many hospitals are served by doctors who are also engaged in general medical

ANALYSIS OF 28 REPLIES.

Personal Questionnaire to Radiologists of Non-Teaching Hospitals.

A.—1. Are you Radiologist to more than one Hospital?	24 Yes/No 4
2. Under which of the following categories does your Hospital X-ray Practice fall?	
(a) Voluntary Hospitals:	
(i) In a large Provincial Hospital with from 200 to 400 beds or more	19
(ii) In a smaller Provincial Hospital with from 50 to 200 beds (recognized as a Teaching Centre for Nurses)	23
(iii) In a Cottage Hospital up to 50 beds	14
(iv) b. Orthopaedic Hospitals	4
c. Municipal Hospitals	19
d. Sanatoria, &c.	2
e. Industrial Clinics	2
B.—Do you carry out Private Practice?	
1. At your Hospitals. If so, at what terms?	26 Yes/No 2
Comments: Legion.	
2. At your own Rooms	22 Yes/No 6
C.—Do you receive any honorarium for your Hospital work?	14 Yes/No 12
D.—Are you able to give the amount of time to your Hospital work that you consider really necessary so that every patient may receive the maximum attention?	8 Yes/No 20
E.—Do you employ Tomography or does the time factor exclude to a large extent this valuable aid to investigation?	13 Yes/No 15
F.—Are you satisfied that you, personally, are being adequately remunerated for the work that you are doing in Hospital?	9 Yes/No 19
If not, what alternative scheme would you suggest?	
Comments: Legion.	
G.—Are you in favour of carrying out your Private work in Hospital and NOT at your own Private Rooms?	14 Yes/No 12+2?
H.—Do you think that any form of Private X-ray Consulting Practice can survive the introduction of the National Health Service?	15 Yes/No 12+1?
In your opinion is it desirable that it should do so?	24 Yes/No 2+2?
I.—Are you satisfied in your Hospitals?	
1. With your equipment?	19 Yes/No 9
2. With your accommodation?	13 Yes/No 15
3. With the adequacy of your Staff?	
(a) Radiographic	16 Yes/No 12
(b) Secretarial	12 Yes/No 16
(c) Nursing, &c.	15 Yes/No 13
4. With the attitude of your Hospital Committees towards expenditure, remuneration and number of Staff?	19 Yes/No 9
5. With the co-operation of your colleagues in the matter of notes and investigations in other fields that would assist the Radiological conclusions...	12 Yes/No 16

Radiotherapy.

In the majority of Non-Teaching Hospitals, Radiotherapy, except for Superficial Therapy—Treatment of Skins, &c.—is seldom justified unless under the direct supervision of a member of the staff of a recognized Therapy Centre, usually a University Centre.

Normally, the Non-Teaching Hospitals, particularly the smaller ones, have no Physicist and in many cases restricted Pathological facilities. They are accordingly often not in a position to make a diagnosis let alone treat cases requiring Deep Therapy and Radium.

Do you agree with this opinion?

25 Yes/No 2
1 No Opinion.

The Depersonalization Syndrome

By H. J. SHORVON, M.B., B.S., D.A., D.P.M.

[This paper has been written in collaboration with Dr. J. D. N. Hill, Dr. E. Burkitt, and Mr. H. Halstead.]

INTRODUCTION.

In his classical paper "On Depersonalization" in 1935 Mayer-Gross [1] commented on the meagre literature despite the widely scattered distribution of the syndrome. The term "depersonalization" was first used by Dugas [2] in 1899, to name a syndrome originally described by Krishaber [3] in 1872 under the title of cerebro-cardiac neurosis. The definition of the term as conceived by different writers tends to be a descriptive one, each stressing particular aspects according to his special approach. Thus Schilder [4] in 1914 says: "The individual feels totally different from the previous being; he does not recognize himself as a person, the outside world appears to him foreign, the 'self' does not behave any more in the former way." Oesterreich [5] views it more from the standpoint of affect, thus: "There is a diminution or complete disappearance of feeling, the individual's sense of living is gone, the central life sense is checked." Janet [6] observes that "depersonalization takes place when the individual does not recognize the maximum of consciousness and of reality, and depersonalization is nothing else but an internal perception of the disturbance in the function of reality, or else a dissolution of attention and therefore a release of automatic activity." Wiersma [7] defines depersonalization as "a suddenly occurring rapidly passing state in which everything in the environment is perceived vaguely and indistinctly. The complaint is not infrequently heard that everything, though well perceived, is with difficulty recognized. The voices of others, and also of the person himself, are plainly heard but not recognized. It is as if the perceptions are duly accomplished, but the associations which they arouse in normal circumstances are not formed. The patients complain that they cannot think properly, that they cannot reflect; they feel dull and dazed, and the examination shows they have difficulty in answering questions".

Krapf [8] says of the syndrome: "The individual expresses himself as strange, his perceptions insufficient, his feelings empty, his thoughts shallow without relief, his acts automatic. It has been remarked for long that the strangeness is a faraway perception.

or surgical practice; (2) that where a doctor is radiologist to one hospital only he usually is of the above type, or else has a whole-time radiological appointment at that particular hospital; (3) that most radiologists on my list serve several hospitals; (4) that a number of men appear to serve far too many hospitals and cannot possibly do their job efficiently; (5) that several serve hospitals in more than one county, some in more than two.

I can foretell some difficulty in dealing with this problem when regionalization comes along—if it does.

When we get above two hospitals, and in some cases in two hospitals also—the number of beds served is in the region of 600 more or less.

Where one man runs two hospitals the question of holidays is so difficult to solve that it usually results in no holidays at all.

The type of hospital is fairly general and varied. Note the lack of radiologists in orthopaedic hospitals and sanatoria—these tend more and more to be dependent for the interpretation of their radiographs upon their own staff, with its limited knowledge.

With regard to the final question on radiotherapy, the answers are overwhelmingly in favour of having a first-rate staff and well-organized radiotherapy departments in our hospitals, specially adapted for this purpose.

On the whole the non-teaching hospitals have put up a good performance and have done, and are doing, their best.

They are *not* in many cases fulfilling the ambitions of their radiologist: (a) Through lack of staff—chiefly medical—and inability of radiologist to give necessary time; (b) shortage of apparatus in many cases; (c) lack of accommodation; (d) lack of funds to provide these; (e) lack of co-operation of colleagues in other fields.

Let me stress that this state of affairs does not apply to the teaching hospitals and to many of the non-teaching hospitals. In the case of the small hospitals perhaps the answer lies in the principle that some of us provincial radiologists have tried to follow out. In the smaller hospitals we cannot attempt to handle all the special cases, e.g. neuro-radiology, because, in the first place, we do not see enough of them. We must be prepared to send these cases to larger centres, university centres or other special centres where they can be adequately handled by a team.

I should like to end with a plea for Refresher Courses, and for frequent meetings to promote not only interest and study in radiology but also to foster a spirit of co-operation and wide understanding amongst us.

The Depersonalization Syndrome

By H. J. SHORVON, M.B., B.S., D.A., D.P.M.

[This paper has been written in collaboration with Dr. J. D. N. Hill, Dr. E. Burkitt, and Mr. H. Halstead.]

INTRODUCTION.

In his classical paper "On Depersonalization" in 1935 Mayer-Gross [1] commented on the meagre literature despite the widely scattered distribution of the syndrome. The term "depersonalization" was first used by Dugas [2] in 1899, to name a syndrome originally described by Krishaber [3] in 1872 under the title of cerebro-cardiac neurosis. The definition of the term as conceived by different writers tends to be a descriptive one, each stressing particular aspects according to his special approach. Thus Schilder [4] in 1914 says: "The individual feels totally different from the previous being; he does not recognize himself as a person, the outside world appears to him foreign, the 'self' does not behave any more in the former way." Oestereich [5] views it more from the standpoint of affect, thus: "There is a diminution or complete disappearance of feeling, the individual's sense of living is gone, the central life sense is checked." Janet [6] observes that "depersonalization takes place when the individual does not recognize the maximum of consciousness and of reality, and depersonalization is nothing else but an internal perception of the disturbance in the function of reality, or else a dissolution of attention and therefore a release of automatic activity." Wiersma [7] defines depersonalization as "a suddenly occurring rapidly passing state in which everything in the environment is perceived vaguely and indistinctly. The complaint is not infrequently heard that everything, though well perceived, is with difficulty recognized. The voices of others, and also of the person himself, are plainly heard but not recognized. It is as if the perceptions are duly accomplished, but the associations which they arouse in normal circumstances are not formed. The patients complain that they cannot think properly, that they cannot reflect; they feel dull and dazed, and the examination shows they have difficulty in answering questions".

Krapf [8] says of the syndrome: "The individual expresses himself as strange, his perceptions insufficient, his feelings empty, his thoughts shallow without relief, his acts automatic. It has been remarked for long that the strangeness is a faraway perception.

or surgical practice; (2) that where a doctor is radiologist to one hospital only he usually is of the above type, or else has a whole-time radiological appointment at that particular hospital; (3) that most radiologists on my list serve several hospitals; (4) that a number of men appear to serve far too many hospitals and cannot possibly do their job efficiently; (5) that several serve hospitals in more than one county, some in more than two.

I can foretell some difficulty in dealing with this problem when regionalization comes along—if it does.

When we get above two hospitals, and in some cases in two hospitals also—the number of beds served is in the region of 600 more or less.

Where one man runs two hospitals the question of holidays is so difficult to solve that it usually results in no holidays at all.

The type of hospital is fairly general and varied. Note the lack of radiologists in orthopaedic hospitals and sanatoria—these tend more and more to be dependent for the interpretation of their radiographs upon their own staff, with its limited knowledge.

With regard to the final question on radiotherapy, the answers are overwhelmingly in favour of having a first-rate staff and well-organized radiotherapy departments in our hospitals, specially adapted for this purpose.

On the whole the non-teaching hospitals have put up a good performance and have done, and are doing, their best.

They are *not* in many cases fulfilling the ambitions of their radiologist: (a) Through lack of staff—chiefly medical—and inability of radiologist to give necessary time; (b) shortage of apparatus in many cases; (c) lack of accommodation; (d) lack of funds to provide these; (e) lack of co-operation of colleagues in other fields.

Let me stress that this state of affairs does not apply to the teaching hospitals and to many of the non-teaching hospitals. In the case of the small hospitals perhaps the answer lies in the principle that some of us provincial radiologists have tried to follow out. In the smaller hospitals we cannot attempt to handle all the special cases, e.g. neuro-radiology, because, in the first place, we do not see enough of them. We must be prepared to send these cases to larger centres, university centres or other special centres where they can be adequately handled by a team.

I should like to end with a plea for Refresher Courses, and for frequent meetings to promote not only interest and study in radiology but also to foster a spirit of co-operation and wide understanding amongst us.

and Olsen and Ruby [33] state that anosognosia may arise in three distinct situations, namely a lesion of the thalamus, a lesion of the thalamoparietal peduncle, or a combination of motor cortical lesion and an interparietal lesion. Anton [34] in 1899 described a condition of failing perception which consisted of Babinski's anosognosia and the lack of recognition of blindness and deafness. In Gerstmann's syndrome [35], or finger agnosia, the body schema is affected by a focal cerebral lesion in one hemisphere only, the hemisphere concerned with the individual finger. This occurs in lesions of the angular gyrus. The patient's psychic condition is good, but may be disturbed for a time. Bender and Kanzer [36] describe a dreamlike state of unreality occurring in a parieto-occipital tumour, with disturbance in the perception of forms, and spatial order of objects, and in the orientation of the patient in space. Russell Brain [37] describes three cases of a distinct form of visual disorientation resulting from a lesion of the posterior half of the right cerebral hemisphere, and characterized by an inattention to the left half of external space. Significant contributions to the problem of disorder of the body image in psychiatry have been made by Gurewicz [38] on the "interparietal syndrome" which is characterized by two types of phenomena; disorders in the body image, and metamorphosis. Bychowski [39] reviews the study of the body image and says the Vienna School attempted to take into consideration the psycho-analytical view-point. This view-point attributes to narcissistic motives the fact that the patient refuses to admit to himself that his extremity is missing. The phenomenon of anosognosia has been related by Pözl [40] and Schilder with the role of repression. It must be pointed out that in all the above neurological conditions, the condition is a *sign* of loss of function which can only be demonstrated by testing. In depersonalization, however, the condition is a *symptom* complained of by the patient; the difference therefore is between a sign and a symptom, or difference between a disorder at the level of behaviour and a disorder at the level of experience.

Clinical Findings.

This investigation is based on a series of 66 cases recently examined and treated in the Sutton Emergency Hospital neuropsychiatric unit, and in the psychiatric out-patient departments of four London hospitals. There was no age selection, but we have excluded severe psychotics and involutional depressives, although we know the symptom is common amongst them. We have confined ourselves almost entirely to cases in which depersonalization is either the presenting symptom, or plays a leading part in the symptomatology, or is a clinical entity, in all of which the patients understand the morbid nature of their state. The value of our selection is that we have a clear picture of the symptoms studied and many cases will fit into no other diagnosis than the depersonalization syndrome. Practically all cases were leading a comparatively normal life prior to the onset. In the history-taking, particular attention was paid to the patient's description of the symptoms, often supplemented by a written account of his attitude to the symptoms. Care was taken as far as possible to avoid leading questions, and a verbatim account of the patient's statements was taken at the interviews. Each case had a full psychiatric investigation, and physique, personality development and intelligence were assessed. Miss J. M. Moore, psychiatric social worker, supplied social and family histories in most of the cases, visited the homes and interviewed near relatives. Special investigations carried out included the Rorschach test in 18 male and 22 female cases, the electroencephalogram was recorded in 23, and Miss Elizabeth Bennett did a series of imagery type assessments. The 66 cases comprise 46 females and 20 males. The youngest age of onset was 10, the oldest 38; the average age of onset in women being 24.5 years, and in men 23.5 years. 20 cases began under the age of 20, 30 cases between the ages of 20 and 30, and 16 cases from 30 to 40. A quarter of the cases had a sudden onset of depersonalization between the ages of 15 and 19. It is impossible to give a composite survey of the duration of symptoms as the majority of the cases are still depersonalized. Some cases have had recurrent attacks of varying duration, others have remained persistently depersonalized for many years with or without marked fluctuations in its course. Thus one patient has had recurrent attacks for twenty-six years, another for twenty-three years, and 7 patients have been persistently depersonalized for seven years. 2 cases have up to date a persistent duration of symptoms of nine years; 1 of eleven years; 2 of thirteen years. One patient has had a fluctuating course over twenty-seven years, and another in a similar way over twelve years. It must be emphasized that affective disorder could not be regarded as primary in these cases. The physique of patients varied in type, but the majority are of asthenic or athletic habitus. A point of possible interest in the previous medical history is that 9 cases had rheumatic fever in childhood and many others had recurrent attacks of tonsillitis and bad throats.

All descriptions of the symptom fall naturally into those of changes of the self, or changes of the outer world. In the latter, attempts to classify cases into those experienc-

Objects seem different, colours weaker, food without flavour." Again Lange [9] gives a good description. He says: "The feeling of belonging to one's own body is lost. The patient feels like an automatic machine, like a statue. The sound of his voice, his face in the mirror seems strange to him. His mental pictures are shadowy. His perceptions do not awaken a feeling of reality, his actions are mechanical, without the feeling of will. Thoughts come and go without personal effort. The patient feels like an apathetic spectator without connexion with his own perceiving and doing."

As Mayer-Gross points out, when depersonalization is referred to one generally includes in addition to changes of the self, changes in the environment, called "derealization" by Mapother.

Depersonalization can occur in any morbid psychological reaction and is common in manic-depressive states, schizophrenia, obsessional neurosis and involutional melancholia, but also occurs in anxiety states and hysteria. It is seen in states of altered consciousness and occurs in encephalitis lethargica [10, 11, 12], in epilepsy [13], intoxication, delirium, hypoglycemia and exhaustion. It has been described in organic conditions such as brain tumour and trauma [14], athetosis, hypoparathyroidism, carbon-monoxide poisoning [15] and mescaline intoxication [16].

The mechanism of depersonalization has been approached from psychological and neurological view-points, and a diversity of theories have been advanced by descriptive psychiatrists, psycho-analysts and neurologists. Mayer-Gross has suggested that it is a dysfunction of cerebral origin, and is a preformed functional response of the brain. He also suggested that modern physiological methods should be used to elucidate the mechanism, and this we have attempted to do. We can only briefly refer to some of the important psycho-analytical views. Gordon [17] broadly describes the syndrome as a converted representation of hidden or repressed emotional consciousness by a special determination. Schilder [18] stresses the shift of the libido in these patients, and its partial concentration on a scrutinizing tendency. Nunberg [19] believes it to represent a loss of libidinal attachment as a result of physical punishment and a narcissistic wound. Sadger [20] states it may be an attempt to escape psychic castration, and Searl [21] regards it as an attempt to escape psychical and physical punishment by possessing the immunity of inanimate objects. Freud [22] makes his first mention of the subject of estrangement and depersonalization in 1937, noting two general characteristics, first, that they belong to the defence mechanisms tending to hide something from the ego—estrangement, or denying a portion of the ego—and secondly, that they are rooted in the early past of the individual. Feigenbaum [23] points out that depersonalization is seen to serve as a means of defence—namely, by projection. Oberndorf [24] has written a series of papers on the subject, stressing four successive mechanisms: parental identification; erotization of thought; identification of such thinking as a characteristic of the parent of the opposite sex; and repression. Wittels [25] also suggests that the important mechanism is the use of identification in the formation of personality. He says: "It seems to me that the cause of depersonalization is an unusually great number of phantom figures, leaving the ego in such a position that it cannot decide which one of the figures has to be acknowledged as its representative. In terms of the libido theory we could say insufficient ego libido is invested in any one of these phantoms. Hence they are all grey and colourless, surrounding a perplexed and swaying personality. In all cases of depersonalization under my observation something was wrong in the infantile relation between the patient and the father. It does seem to me as though the super-ego is responsible for the disintegration of personality by condemning all of the phantoms without exception as unreal."

Neurologists have attempted to explain the syndrome in terms of local cerebral function, although no pathological changes are found in cases of depersonalization as we understand them. They point out the close association of depersonalization and the phenomena of *déjà vu*, and also the connexion between disturbances in the "body schema" and its representation in the cortex [26, 27, 28, 29]. This "body schema" or "body pattern" is the concept which a person has of the image of his own body, or that of another, and the spatial relations of the parts of the body to each other. The body image is intimately associated with the cerebral cortex especially the inferior parietal, marginal, and angular gyri, and in the case of focal lesions loss of the body image may occur, but the patient may not be aware of its disturbance; nor need it interfere with motor function. Such lesions do not necessarily affect projection tracts, but involve association systems and cause genuine disturbance of the psyche [30]. Thus, in anosognosia, first described by Babinski [31], in which condition an individual is unaware of his own disease, there is a specific defect in body image. Defects in body image are common in neurological and psychiatric conditions. Barkman [32] showed that the hemiplegic anosognosia described by Babinski, was due to a lesion of the right thalamus;

the pregnancy. 6 cases followed operations (with anaesthesia), and a few followed some days after minor injuries to the head. One pregnant woman became depersonalized whilst looking at some pictures in the National Gallery, after she had been taking massive doses of abortifacients and had given up the idea of successfully inducing an abortion. Another pregnant woman stated that it followed the taking of salicylates, and another patient was taking 15 grains of thyroid daily to reduce her weight before the onset of symptoms.

Unlike most psychiatric conditions some patients find that when they concentrate the symptom recedes and when they relax it returns; as one patient says: "I concentrate and get things back a little, but the strain is too strong and as soon as I relax everything has gone again. I felt an attack coming on after my third confinement, but beat it this time by keeping my mind working." One young man had been almost continuously depersonalized for eight years. He said he felt worse when relaxed and all right if occupied. He supposed he was the only person who would welcome, for instance, a fire, as the excitement would relieve his symptoms. The happiest period of his life was when the Gestapo were after him and he was hiding or moving about, living on wheat ears and dry meat. He was symptom-free then.

Our data fully substantiates the attitude taken by Mayer-Gross that it is possible to find support for a variety of theories about depersonalization by selecting suitable descriptions. He describes under the heading of theories from incomplete data the following:

TABLE I.—TOTAL CASES 66.

	No. of cases		No. of cases
Altered time perception ...	22	Loss of feeling accompanying action	30
Altered space perception ...	21	Disturbance of memory ...	6
Lack of affect ...	22	Altered range of consciousness ...	20
Bodily change ...	45		

(1) Altered experience of time (Lewis [41]). (2) Changes in perception of space. (3) Lack of feeling. (4) Subjective experience of bodily change. (5) Loss of the specific feelings which accompany action (Loewy [42]). (6) Disturbances of memory. (7) Increased self-observation (Schilder). (8) Changes of clearness and range of consciousness and it seemed to us that equally we might add (9) Disturbances of autonomic function.

Professor Aubrey Lewis has pointed out that time consciousness "is an aspect of all conscious activity; it is essential to all reality. In *déjà vu* there is a brief inability to actualize the present, which in consequence is projected into the past". Of time disturbances in depersonalization he says: "They illustrate many of the outstanding features of the disorder; the inability to evoke the past readily or clearly, to distinguish the present from the past or future; there is paradoxically the increased quickness with which time passes though it seems to drag along, the seeming remoteness of the recent past, the unconfirmed feeling of inability to judge the length of time. In depersonalization there is a change in space and time consciousness which may be expressed in various forms."

We have found altered experience of time in 22 cases and they fit in well with Professor Lewis's observations. One patient stated: "The times have gone. I can remember but there is nothing in that. The day is gone and it is empty. Time is gone, is a blank I have been here ten days and it seems I've been here no time at all." Another patient said: "When I do anything it seems such a long time ago. If I do anything in the morning it seems like weeks ago. Time does not mean anything; it seems long drawn out."

Twenty-one cases described changes in perception of space. For example: "Everything around me was far away and tiny", or "When I walk the ground seems to be high up. If I put anything down it seems to come towards me", or "The garden simply receded and looked like a scene on the stage."

Twenty-two cases described lack of affect. "The emotional part of my brain is dead. My feelings are peculiar, I feel dead. Whereas things worried me nothing does now. My husband is there but he is part of the furniture. I don't feel I can worry. All my emotions are blunted."

Forty-five cases showed subjective experience of bodily change. "Queer sensations connected with my breathing. I am conscious of not breathing like other people and feel myself on occasions taking deep breaths which don't come easily. My head and my breathing is in a muddle."

Thirty cases seemed to show loss of the specific feelings which accompany action. "If I laugh when somebody makes a joke it is automatic. There just doesn't seem anything there." "I sing but I can't get the feeling of happiness. I lie in bed and get up and

ing a loss, those a change, and those an addition to the outer world, showed that addition is very rare, and that the same patient would at times speak as if the environment had something missing in it, and at others as if the quality of his perceived experience had changed. Again there was no clear distinction to be drawn between derealization and depersonalization. Whereas we have not found derealization without depersonalization, the reverse occurred in a few cases. In the majority, the patient would complain at different times in terms of altered experience of self, or of the outer world, but would lay emphasis on one or the other. In our attempts to elucidate differences of this type we have recorded verbatim patients' descriptions of their symptoms, but in practice it becomes clear that patients have the greatest difficulty in communicating their experiences. Such communications do not readily lend themselves to objective divisions of this sort. This may be due either to the complex nature of the experience, or possibly to the fact that it is difficult to put into words. This may explain why the best descriptions are given by the most intelligent patients.

Fear, and the experience of being misunderstood, or being thought insane, have led many patients to suppress this symptom, and to complain of accompanying somatic changes. Such patients are often diagnosed as affective disorders.

Out of the 66 cases, 61 had a sudden onset, 3 cases were doubtful and in 2 the onset was gradual. Intelligent people describe the onset of the experience of unreality in a number of different ways, or in a composite way which would fulfil the criteria of more than one theory. Thus one patient said: "Suddenly everything was strange, unreal, and I was a different person." Another said: "Everything suddenly went black. It was as though something had snapped, and from then on things seemed different." A few random descriptions include: "I suddenly felt peculiar." "I suddenly felt I was dead." "It was as if my brain turned right over, and it left me with a dreamy confused and bewildered feeling." "I suddenly could not think what I was saying. I could not focus. I was talking to someone and yet I was there and not there." "I wondered whether I looked the same. I kept repeating to my husband: 'Am I the same? do I look the same?'" "I was walking down the stairs one day when half my mind seemed to go. I kept looking at things to see if anything went back to normal, to see if they were in their original perspective."

In some cases the symptom is first of momentary duration, and then may recur at intervals, lasting longer each time, finally becoming stationary; or the condition may continue unvarying. The symptom frequently sets up a panic state, and it is common for patients to complain from that time of fears of insanity, of impending death, and particularly of fears of going out alone, and inability to travel. The initial onset is frequently accompanied by overbreathing or difficulty in breathing, a feeling of faintness without an actual faint, and numerous somatic symptoms of anxiety.

An interesting observation is the frequency with which depersonalization begins during a period of relaxation following prolonged fatigue or psychological stress or both. In our series it is commonly found to commence after such conditions, for instance when on holiday, or in the change over from an arduous or unpleasant job to a lighter or more congenial one, or in soldiers during leave, after demobilization, or awaiting return home from abroad. One patient had a very worrying time over the question of marriage which she did not desire, and the attack began a week after her fiancé was sent overseas; whilst another patient who had badly missed her soldier-husband had an attack when he was home on leave. One patient, after being evacuated from home for years, had tramped the streets of London for weeks trying to find a place in which to live, and the attack came on four days after resting at her sister's home. Another patient had had little rest during the "blitz" and became depersonalized soon after evacuation to the country. Other cases followed broken engagements, and one after the termination of a homosexual love-affair of many years' duration and of a very unsatisfying nature. An obsessional individual with fears of dirt contracted pediculi pubis, and he went through severe stress; he became depersonalized during a period of intense relief following the cure of his skin trouble. An obsessional young woman who was very harassed by a nagging mother-in-law, and worried by her infant's thrush, became ill after she left for her own home and the baby's condition cleared up. A highly intelligent, strongly obsessional man of 31 who obtained a first-class honours degree in economics after intensive study in the evenings—he was a wage earner by day—became preoccupied with abdominal pains due to a spastic colon and mucus colitis. His condition was complicated by attacks of migraine and after an unsuccessful course of analytical treatment he was admitted to hospital in a tense agitated state. He responded well to physical treatment and rest, but became depersonalized a month later. 8 cases followed within two to six weeks of parturition. In these cases there had been severe psychological and physical stress during

the pregnancy. 6 cases followed operations (with anaesthesia), and a few followed some days after minor injuries to the head. One pregnant woman became depersonalized whilst looking at some pictures in the National Gallery, after she had been taking massive doses of abortifacients and had given up the idea of successfully inducing an abortion. Another pregnant woman stated that it followed the taking of salicylates, and another patient was taking 15 grains of thyroid daily to reduce her weight before the onset of symptoms.

Unlike most psychiatric conditions some patients find that when they concentrate the symptom recedes and when they relax it returns; as one patient says: "I concentrate and get things back a little, but the strain is too strong and as soon as I relax everything has gone again. I felt an attack coming on after my third confinement, but beat it this time by keeping my mind working." One young man had been almost continuously depersonalized for eight years. His condition was complicated by attacks of migraine and after an unsuccessful course of analytical treatment he was admitted to hospital in a tense agitated state. He responded well to physical treatment and rest, but became depersonalized a month later. 8 cases followed within two to six weeks of parturition. In these cases there had been severe psychological and physical stress during

Miss Elizabeth Bennett gave imagery tests to 16 cases. She reports that the majority of these patients are predominantly visualizers, a finding which is of no significance, since this is by far the most frequent type in the general population. A few patients have complained of loss of visual imagery, and in two cases this is considered to have been genuine and specific. In the remainder, however, it was found to be a part of a general difficulty in concentrating attention; to a marked visualizer, such a difficulty would naturally be expressed in terms of loss of visual imagery. Investigations of the reality sense showed that in the majority of cases where the external world appears unreal, it appears so equally in all sense modalities. In two cases, however, visual perceptions seemed to be especially affected, things heard or touched retaining their reality quality. Tests for body image showed that the majority of patients did not locate themselves in any particular part of the body. Among those who did, the head was the most favoured site. There were some exceptionally vivid visual images of structural damage to the brain, which damage was equated with irreparable loss of the self.

Our patients use the terms "as if" or "as though" showing there is no delusional content, but remarks are made at times which suggest the basis for the formation of secondary delusions, hallucinations, and ideas of reference in obviously psychotic patients. Thus one patient stated: "I have a feeling I am speaking very loudly to people and they are looking at me in a surprised sort of fashion. This is a silly idea to explain, but I have the feeling that people, even when I am not speaking, are looking at me in surprise" so illustrating the beginnings of ideas of reference. Another patient similarly failed to return to work because her workmates commented on her appearance. "I pick up things said by others. I take notice of all nonsense although I know it is silly." Another patient showed the germs of delusions and hallucinations. Something inside him said "Hope is gone". He felt he was a strange monster and had distressing somatic symptoms such as things flailing about inside him and others which were indescribable".

Hysterical phenomena such as overbreathing, hysterical tetany, or difficulty in swallowing may be a prelude to depersonalization; they may be intermingled with symptoms of depersonalization or it may be expressed as such symptoms, and it is relatively common for hysterical behaviour, and rarely psychogenic amnesias, to follow improvement of the depersonalized state.

TABLE II.—TOTAL CASES 63.

<i>Previous personality.</i>							
	No. of cases	%			No. of cases	%	
Obsessional traits...	56	88	Hysteria	13	20		
Anxiety	35	55	Migraine	24	38		
Hypochondriasis	8	13	Déjà vu	39	62		
Abnormal father relationship				32 out of 48 cases			

As already stressed the type of case we are presenting shows the depersonalization syndrome as a more or less distinct clinical entity with a sudden onset in non-psychotic patients. A study of the previous personality in these patients is revealing. 56 out of 63 patients (or 88%) showed an obsessional personality, 27 (or 43%) mildly so, and 29 (or 46%) markedly so. The great majority of cases therefore tend to be over-conscientious, rigid, ruminative individuals with phobias and a tendency to compulsions. 35 out of 63 (or 55%) have always been anxious individuals. 8 patients (13%) showed previous hypochondriasis and 13 (20%) had hysterical trends. During the illness 45 patients (71%) exhibited an obsessional state, and 37 (59%) were depressed. It is surprising, despite the alleged significant relationship between migraine and obsessional personality, that 24 out of 63 (38%) suffered, or suffer, from migraine and there is an immediate family history of migraine in 13 cases (21%). 10 cases in the series gave a history of migraine in the family although not affected themselves. An interesting clinical observation is that many cases when questioned state that the migraine attacks ceased with the onset of depersonalization. Previous writers, such as Oberndorf [43] and Schilder [44], stressed the close association between the phenomena of *déjà vu* and depersonalization. 39 cases out of 63 (62%) in our series experienced this, the majority frequently. An actual history of depersonalization in the family is rarely obtained, but striking cases do occur. In only 2 cases were such histories obtained. There is a history of allergy in some form in one member of the family in 11 cases, and in only 2 cases is there any family history of chorea. 13 patients out of 63 give a personal history of allergy.

In the mechanism of depersonalization the father relationship has been stressed by psycho-analysts. An investigation of our cases shows that of the 48 cases on which we could obtain information about the father-child relationship, 32 patients were fearful and frightened of their father in childhood, and used various expressions such as harsh, strict, bad-tempered, without affection, when talking about this parent. 16 patients stated

feel all numbed but I do my work." "I am still here now and talking to you and touching things but not in the same way as before I was ill."

Six cases showed disturbances in memory. "If I go outside I shall not remember you. I have clothes but I can't memorize them, unless I go and strain and look at them."

Self-observation although common enough is occasionally expressed in a striking manner: "It is as if I was looking inside my head instead of outside. I seem to be thinking always inside of me instead of out of me." "I suddenly seemed to see myself. I am conscious of my hands."

Twenty cases complained of changes of clearness and range of consciousness. "I just sink into a kind of unconsciousness. I am just conscious enough to know that things are going on around me but nothing seems to register." "I am in a daze." "I seem to be looking through a mist." "Muzzy sensations." "In a dream." "Dopey." "In a fog"—are common expressions.

Disturbances in autonomic function are common in our series. Frequent expressions are: "I have difficulty in breathing and an empty feeling in the pit of the stomach." "A choking sensation and difficult to breathe with giddiness as if I am going to faint." "My stomach shakes."

The number of cases and quotations illustrating the disturbances in function integrating the personality have been obtained from the case records, and must obviously represent minimal percentages of the total cases. Individual cases describing some of these disturbances probably experience some other changes but have omitted to mention them at interviews, particularly so because of the care we have taken to avoid leading questions. A few of our cases show disturbances in all the tabulated features. Having presented selected data from patients' accounts which support well enough the theories of depersonalization mentioned, we now wish to emphasize that the complaints are not restricted in this way. The actual expression of the symptom is undoubtedly dependent on the intelligence, temperament and cultural background of the patient.

The range of actual experience of depersonalization varies from mild changes in "self" to the extreme of feeling two persons, and it is worth quoting some verbatim accounts. A young woman stated: "I can't think it is me. I used to feel I was someone. It never entered my head I was someone else, as though I had changed. I must be someone, I am someone, everybody else feels someone, but I am not myself. I suddenly felt I am in half, there is two of me. The two halves of my body felt they had become apart."

As Mayer-Gross pointed out, cases of severe bodily depersonalization may be unaccompanied by derealization. One young man of 20 said: "I can't seem to find my actual self. I feel as though my deliberations are those of a public body or corporation rather than those of a person. I used to say 'we' rather than 'I'. It is as though I had transcended personality, as if 'myself' had receded to an image which I regarded objectively, and which is not identified with the whole of me". Another patient stated: "I am not living in a world at all. When looking in a mirror I have to keep telling myself the reflection is mine. It's like looking at another person."

Depersonalization of parts of the body, especially head or limbs, are very common. Descriptions include: "The top of my head is popping and buzzing and then it seems to go all numb." "I could look down at my hands and see them writing but they don't seem to belong to me."

Patients frequently describe the experience of something between their eyes and the outside world—"curtain", "blind", "fine wire netting", "fine mesh", "glass wall" are some of the expressions used, and it is common to complain of circles before the eyes. This is bound up with descriptions of experience of change in the outside world that is, derealization. "If I am walking along, round things look distorted and something different. When walking it is as though there is nothing there. There seemed to be some kind of barrier between me and the others, it was almost as if I were under water and I could just see distorted shapes around me. In fact, the people and things around you seem as unreal to you as if you were only dreaming about them." Or "I look at people, the sun, the flowers, everything looks different." "Through the eyes I look out at a world that might be a picture of the world, of objects vaguely unreal till I touch them—a mirrored reflection."

Some patients complain vividly of their inability to visualize. "When you walk into a room you can see a woman there but you have also a mental picture of the room and that's what I don't have. I can see the furniture, but I can't make a mental picture." "One of my chief worries is the fact that I cannot make any mental picture. If I shut my eyes, for instance, it is like a complete blackout, there are no thoughts coming through at all."

Miss Elizabeth Bennett gave imagery tests to 16 cases. She reports that the majority of these patients are predominantly visualizers, a finding which is of no significance, since this is by far the most frequent type in the general population. A few patients have complained of loss of visual imagery, and in two cases this is considered to have been genuine and specific. In the remainder, however, it was found to be a part of a general difficulty in concentrating attention; to a marked visualizer, such a difficulty would naturally be expressed in terms of loss of visual imagery. Investigations of the reality sense showed that in the majority of cases where the external world appears unreal, it appears so equally in all sense modalities. In two cases, however, visual perceptions seemed to be especially affected, things heard or touched retaining their reality quality. Tests for body image showed that the majority of patients did not locate themselves in any particular part of the body. Among those who did, the head was the most favoured site. There were some exceptionally vivid visual images of structural damage to the brain, which damage was equated with irreparable loss of the self.

Our patients use the terms "as if" or "as though" showing there is no delusional content, but remarks are made at times which suggest the basis for the formation of secondary delusions, hallucinations, and ideas of reference in obviously psychotic patients. Thus one patient stated: "I have a feeling I am speaking very loudly to people and they are looking at me in a surprised sort of fashion. This is a silly idea to explain, but I have the feeling that people, even when I am not speaking, are looking at me in surprise" so illustrating the beginnings of ideas of reference. Another patient similarly failed to return to work because her workmates commented on her appearance. "I pick up things said by others. I take notice of all nonsense although I know it is silly." Another patient showed the germs of delusions and hallucinations. Something inside him said "Hope is gone". He felt he was a strange monster and had distressing somatic symptoms such as things flailing about inside him and others which were indescribable".

Hysterical phenomena such as overbreathing, hysterical tetany, or difficulty in swallowing may be a prelude to depersonalization; they may be intermingled with symptoms of depersonalization or it may be expressed as such symptoms, and it is relatively common for hysterical behaviour, and rarely psychogenic amnesias, to follow improvement of the depersonalized state.

TABLE II.—TOTAL CASES 62.

		<i>Previous personality.</i>					
	No. of cases	%		No. of cases	%		
Obsessional traits...	56	88	Hysteria	13	20		
Anxiety	35	55	Migraine	24	38		
Hypochondriasis	8	13	Déjà vu	39	62		
Abnormal father relationship			32 out of 48 cases				

As already stressed the type of case we are presenting shows the depersonalization syndrome as a more or less distinct clinical entity with a sudden onset in non-psychotic patients. A study of the previous personality in these patients is revealing. 56 out of 63 patients (or 88%) showed an obsessional personality, 27 (or 43%) mildly so, and 29 (or 46%) markedly so. The great majority of cases therefore tend to be over-conscientious, rigid, ruminative individuals with phobias and a tendency to compulsions. 35 out of 63 (or 55%) have always been anxious individuals. 8 patients (13%) showed previous hypochondriasis and 13 (20%) had hysterical trends. During the illness 45 patients (71%) exhibited an obsessional state, and 37 (59%) were depressed. It is surprising, despite the alleged significant relationship between migraine and obsessional state, that 24 out of 63 (38%) suffered, or suffer, from migraine and there is an immediate family history of migraine in 13 cases (21%). 10 cases in the series gave a history of migraine in the family although not affected themselves. An interesting clinical observation is that many cases when questioned state that the migraine attacks ceased with the onset of depersonalization. Previous writers, such as Oberndorf [43] and Schilder [44], stressed the close association between the phenomena of *déjà vu* and depersonalization. 39 cases out of 63 (62%) in our series experienced this, the majority frequently. An actual history of depersonalization in the family is rarely obtained, but striking cases do occur. In only 2 cases were such histories obtained. There is a history of allergy in some form in one member of the family in 11 cases, and in only 2 cases is there any family history of chorea. 13 patients out of 63 give a personal history of allergy.

In the mechanism of depersonalization the father relationship has been stressed by psycho-analysts. An investigation of our cases shows that of the 48 cases on which we could obtain information about the father-child relationship, 32 patients were fearful and frightened of their father in childhood, and used various expressions such as harsh, strict, bad-tempered, without affection, when talking about this parent. 16 patients stated

that their childhood was satisfactory or that their father was good to them. This preponderance of an unsatisfactory parent-child relationship is significant.

Rorschach Findings.

We discussed various ways of obtaining supplementary data on personality by psychometric methods. It was finally decided to use the Rorschach test.

TABLE III.—RORSCHACH TEST.

Aspects underemphasized				Aspects overemphasized			
		No. of cases	%			No. of cases	%
Colour responses...	...	18	48	Narrow range of content	...	18	48
Kinaesthetic responses	...	29	73	Failure—one card or more	...	10	25
Texture responses	...	20	50				
Form responses	...	32	80	Rare and minute details	...	12	30
Anatomical-sexual responses	...	13	32	Orderly-rigid approach	...	26	65
18 cases (45%) have a lack (imbalance) of colour in the colour-kinaesthetic ratio, despite the under-emphasis of the latter.							

Protocols were taken, individually, from 18 men and 22 women, all unselected. The ages ranged from 20 to 44 (average 28) for the men, and 15 to 48 (average 30) for the women. The spontaneous record was followed by the usual inquiry, but there was no "Testing of Limits".

Looking at the results, it is that of constrictive controls a whole with all its interrelated parts, the general impression. Some of the signs were: (a) of a kind associated with the obsessive-compulsive personality (cases), over-emphasis on rare and excess of concepts determined purely by shape (in 25% of cases), failures to respond (25% of cases) and minute details (30% of cases), the high percentage of responses, the orderly or rigid way of dealing with the location categories, and the restricted range of the subject-matter (in dealing with the location categories, and regard to accuracy of form, and there was a 35% of the cases). Many were medical, over-thoroughly before surrendering them, with a distinct compulsion to deal with the answers, e.g. "It could be a bat or a butterfly"; or in direct in the frequent answers, e.g. "It is a . . . ?" or "It is a . . . isn't it?"

The group as a whole is intellectually superior as shown by the Rorschach test.

The personality-balance on a global view of the test indicates by the Rorschach test are two indices to be taken into account: (a) the ratio of human kinesthetic responses, and (b) the ratio of animal movement to texture responses. The former is said to reflect conscious tendencies, and the latter the more instinctive or automatic inclinations not fully accepted by the individual. It also indicated the direction of the response, but this is overruled by the second index, from which we infer the following: 35% of the group are introverts, 17% ambiverts, 18% extraverts, while 30% show a balance of tendencies, the basic introverted trends being masked by pseudo-extraversion. Movement responses are inadequate and the ratio of animal to human responses in this area is more than 2 to 1, a balance normal up to puberty but abnormal in the adult. Thus, we may infer emotional immaturity, an unwillingness to fulfil the adult role. The question is left open as to whether the immaturity is a regression due to psychic trauma.

Whereas the group produced 45% of its responses to the three brightly coloured cards, only 9.5% of the total were determined by colour, either wholly or partly. Composite reaction times were over-long for these cards, and many cases of preference for the grey cards as being less of a strain. This is held to indicate that patients were attracted towards reality but found difficulty in dealing with it.

The two extremes—of whole answer on the one hand, and tiny or rare details on the other—were over-emphasized in contrast to the more obvious areas of the test. There was a general shortage of popular responses. This suggests a lack of awareness of everyday matters.

Anxiety is displayed notably through the form of the cases as against the "Blood" or "Inferno" type.

through the different Rorschach responses, and more especially the form of the colour and the shading in check, with occasional hostilities, found in the

coming up for the kill, lions tipped out of an airplane, caterpillar impaled and split open, a horrible beetle that you squash and it cracks." Responses emphasizing the horrible or evil nature of the things seen were fairly common.

Four cases remarked on a feeling of being drawn down or falling towards the blots, and staring eyes were common.

32% of the cases were scored for significantly high anatomical responses, indicating, in a lay group such as this, body preoccupations.

Card VI of the Rorschach Test produced abnormal signs such as long reaction times, low productivity, failures, &c. As this card is known to be weighted for sex, we may infer sexual disturbance as a noticeable characteristic of the group.

Perseveration was another sign of constriction noted; in most instances it was recognized by the patients.

In conclusion, we may say that the Rorschach pattern of this group of patients has little in common with that found in organic cases, but has most of the features indicative of psychoneurosis with a high quantitative measure of maladjustment. This is expressed mostly in a formal, compulsive attitude to life, with the more positive emotions tightly repressed or denied.

E.E.G. Findings.

Electro-encephalographic investigations can provide us with data relevant to the problems of depersonalization from a number of different points of view. First, a disorder of attention, either to visual perceptions or to visual imagery, would be related to the failure of the alpha rhythm to block to stimuli. The equal presence of alpha rhythm on the two hemispheres, having a mainly post-central distribution and blocked by visualization, is a demonstration of the normal resting function in the visual association areas. Failure of blocking is seen in normal non-visualizers, and in many patients with reversible or irreversible deterioration of attentive capacity from any cause. In the 23 cases of depersonalization examined in this series, all showed normal blocking of the alpha rhythm to opening the eyes. The alpha rhythm in one case, showing a poor response to this, blocked normally when told to look. In this instance, as in others tested, the alpha blocking during mental arithmetic was normal. We were able, in one case, to demonstrate the return of the alpha rhythm while the eyes were open when the attention was diverted, first to auditory stimuli, and then to tactual stimuli. These findings provide evidence of a normal physiological functioning of the cortical cells, and their inter-connexions in those brain areas serving visual perception and in particular those in Vogt's area 19.

The second point of interest is the comparison of the group as a whole with the normal population and related psychiatric groups. 13 of the 23 cases examined had minor abnormalities in the E.E.G. compared with the standards of normality at present accepted. This percentage abnormality (over 50) is extremely high for any non-organic group with the exception of the chronic psychotic mental hospital population. The figure is about twice as great as that found by most workers for any mixed psychoneurotic group. While 5 of the E.E.G. + group had received convulsive therapy, none of the E.E.G. - group had done so, and no doubt this is a contributory factor in making for E.E.G. abnormality. However, when one excludes these, about 35% are still abnormal, and this is still an unusually high figure. The age factor is also probably significant, although the numbers are too small for certainty. In the whole group the ages ranged from 19 to 42 but the average for E.E.G. + cases was 26 years, and for the E.E.G. - cases 32 years. The significance of the age factor is enhanced by the fact that the 6 E.E.G. + cases showing instability of rhythms to overbreathing were all at the young end of the age range, the average being 23 years.

Examination of the abnormalities themselves shows them to be of the minor sort. Only one case had a focal abnormality and he was known to have had migraine. The group was heterogeneous, in that some had slow rhythms, some fast, and others fast and slow. None, however, showed paroxysmal activity and none rhythms at less than 4 c/sec. In none was any relationship to the epileptic group found, nor any evidence of an organic process such as is given from the presence of a focus or from the characters of the wave forms. The increase of slow rhythms during overbreathing (6 cases), and their reduction by breathing CO₂ and amyl nitrite (2 cases) is in conformity with the findings in other cases in whom a physiological dysfunction can be inferred with greater certainty. Repeated examinations made on a few cases during the illness and after recovery showed the patterns to be constant in appearance. Reduction of slow activity by chemical action had no effect on the symptom, and for these reasons, as well as from general principles, there is no reason to believe that the E.E.G. abnormalities are in any way directly related

to the mechanism of depersonalization. It would seem that they must be regarded in the same light as the E.E.G. abnormalities in the case of the psychoneurotic cases. The abnormalities are minor deviations from the normal pattern, heterogeneous variations which are more frequent in the younger patients, and an expression of constitutional or developmental variation from the normal.

Response to Treatment.

Scant attention has been paid in the past to the question of treatment in cases of depersonalization, particularly in non-psychotic cases. In involuntional depression and schizophrenia the symptom tends to disappear with the improvement in the psychosis. In the group with which we are concerned we find, generally speaking, that most physical methods of treatment may improve the affective state but seem to have little or no effect on the unreality feelings. Psychotherapy and analytical methods, of course, have been used extensively; but in stubborn cases show little result. We have attempted an evaluation of results and have classified them according to the responses to convulsion treatment, continuous narcosis, benzedrine, epanutin, vasodilators and abreaction techniques especially, with the use of ether, or a combination of cardiazol and ether. On one case Dr. Dalton Sands has had a prefrontal leucotomy performed. Psychotherapy has been used in all cases in conjunction with the physical methods employed.

E.C.T.—39 cases have been treated with a course of electro-shock therapy. This is a treatment commonly used, and it is important for the results to be carefully assessed. The number of treatments given varied from three to fourteen. One of the cases states his depersonalization started after a course of E.C.T. Of the remaining 38 cases only 2 lost their depersonalization, 4 were improved, 1 was temporarily improved, there was no change in 22 cases, and 10 patients stated they were worse. Thus, 32 out of the 39 patients were unchanged or worse after the treatment. Of the 32, 5 were less depressed, 10 slightly improved, and 17 remained the same. Of those that recovered or were much improved, 2 were post-puerperal, 2 were recurrent depressives, and 2 were hysterics with depression.

There is, therefore, little or no place for the use of E.C.T. in the treatment of depersonalization where it is a clinical entity. The treatment is of value for endogenous depressions, but in such cases it is the depression which is relieved and the depersonalization clears up with it.

Continuous narcosis.—15 cases had a full course of continuous narcosis with sodium amylal and paraldehyde. 7 showed no change, 4 appeared worse, and 3 were relieved of their tension with no change in depersonalization. One patient recovered. He was a case of recent onset with marked obsessional and anxiety features. The results on the whole are poor.

Benzedrine and epanutin.—39 cases had a course of treatment with benzedrine 10 to 20 mg. daily. 27 showed no change. 10 cases were improved, generally slightly and only in their affect; one was much improved, but there was a probability that epilepsy complicated this illness, and another case showed improvement in derealization but not in depersonalization. Epanutin in increasing doses was tried with 23 patients, 18 without effect and 5 showed slight improvement. An epileptic patient had her fits controlled by benzedrine and epanutin, but she had a sudden onset of depersonalization when under treatment.

Vasodilators.—These had little or no effect. 13 cases were treated with 50 to 100 mg. t.d.s. of nicotinic acid for weeks without effect. Intravenous injections of 10 c.c. Afenil (CaCl_2 -urea) were given daily to 7 patients for a fortnight. There was a slight relief of anxiety in 2 cases, and no change in the remainder.

TABLE IV.—RESPONSE TO TREATMENT.

	Total cases	Results			
		Recovered	Improved	No change	Worse
E.C.T.	39	2	4	23	10
Contin. narcosis	15	1	0	10	4
Benzedrine	39	0	2	37	0
Epanutin	23	0	5	18	0
Nicotinic acid	13	0	0	13	0
CaCl_2 urea	7	0	0	7	0
Insulin comas	0	0	0	0	0
Leucotomy	1	1	0	0	0
Ether abreaction	14	4	7	3	0

Ether abreaction.—It occurred to Dr. William Sargant and myself [45] that abreaction ~~ether~~ ^{other} means of excitation might be attempted in the group.

There were some interesting results in the 14 cases tried. 4 patients lost their depersonalization dramatically and have remained well. One was a female of 29 who was depersonalized for six months and becoming agitated and depressed. She was abreacted over an incident in a bus which mounted the pavement. Great excitement was deliberately stimulated till the patient went into a state of temporary "collapse" [45] and when she came round there was immediate and lasting loss of depersonalization. Before this she had had a course of E.C.T. without effect. The other case was a man of 44 who had suffered depersonalization for six years and was intensely anxious. E.C.T. had failed to relieve him. He had a phobia of dirt and was abreacted over an attack of pediculi pubis which had preceded his depersonalization. He showed tremendous affect. The first abreaction ended in violent excitement, but as he did not reach the point of collapse he was immediately abreacted again. This culminated in a short period of stupor, with lasting relief of symptoms. A third patient who became depersonalized three weeks after her first child was born abreacted violently over her confinement experiences with good effect. The fourth patient was a young man who was predominantly derealized; his symptoms cleared after a general abreaction. Among other cases of this group are, one obsessional patient of 20 persistently depersonalized since the age of 13 showed little affect under ether, but he reported "minutes of normality" for some days; and an agitated obsessional woman of 24 on coming round showed rapid fluctuations of unreality and normality. A girl of 20 in the W.R.N.S. was abreacted over an incident in a classroom when she was unable to answer a question and became depersonalized. She became very excited and lost her depersonalization for several hours. She relapsed and was again abreacted with only momentary improvement, and then became anxious and dissociated. Another patient of 25 who had been depersonalized for eleven years, following a moderate ether abreaction, lost his symptoms of derealization with diminution in intensity of depersonalization. This was only temporary. A patient who was profoundly depressed and depersonalized also showed a momentary loss of the symptom, whilst 2 others stated the next day that they felt something had lifted, and were relieved but still depersonalized. 3 patients failed to show any excitement under ether and there was no change. Anxious patients tend to respond; depressed patients remain apathetic.

Cardiazol.—Cardiazol fits were reported by Schilder [46] to produce some useful results. We have not been able to investigate this finding adequately but 1 case had no result from 5 fits and 2 others, who had one and two fits respectively, showed no change. The injections were given after E.C.T. had failed. The result in a fourth patient, however, was very interesting. He had been depersonalized for three years and was given an intravenous injection of 6 c.c. of cardiazol whilst he was in a light stage of insulin coma. This was insufficient to produce a fit but he showed very marked twitching and generalized excitation. When the hypoglycemia was subsequently interrupted by intravenous glucose he said he "felt lighter and everything appeared normal. He could see the trees, &c., as they used to look". He remained well and some days later said: "Everything is bright, as if I have come out of a dark room into a bright room. Something has lifted—gone. I used to feel as if I was in two, but now I am whole." This result may have some similarity to the good results obtained by the induction of excitation under ether.

Modified insulin.—Modified insulin produced physical improvement in most patients with increase in weight, but had no effect on depersonalization. *Deep insulin* comas in 6 cases similarly produced no benefit.

Leucotomy.—One patient had prefrontal leucotomy performed. She suddenly became depersonalized in 1938, three weeks after a confinement, followed by depression and loss of interest in her baby and family. She remained in this state, and entered a mental hospital in 1942 where she was given five cardiazol treatments without benefit. Later she had a course of ten E.C.T.s and a course of sleep treatment again without improvement. In 1944 she was in another mental hospital and treated unsuccessfully with thyroid extract. She remained persistently depersonalized with marked emotional blunting, and said she felt empty and dead, automatic, time meant nothing, and that nothing came from her mind. Her personality was obsessional. She was admitted to hospital under Dr. Sands. A course of analytical treatment produced no change, neither did deep insulin comas and she became agitated, tearful and emotional. In March 1945, when aged 39, with a history of seven years' continuous depersonalization, a leucotomy was performed by Mr. Wylie McKissock. For a time there was little change except for an easing of tension, but later she began to lose her depersonalization. She continued to complain at intervals of depression and lack of feeling towards her family but there was a marked improvement nine months after the operation. Except for some irritability and temper she has now

to the mechanism of depersonalization. It would seem that they must be regarded in the same light as the E.E.G. abnormalities in the case of the psychoneurotic cases. The abnormalities are minor deviations from the normal pattern, heterogeneous variations which are more frequent in the younger patients, and an expression of constitutional or developmental variation from the normal.

Response to Treatment.

Scant attention has been paid in the past to the question of treatment in cases of depersonalization, particularly in non-psychotic cases. In involutional depression and schizophrenia the symptom tends to disappear with the improvement in the psychosis. In the group with which we are concerned we find, generally speaking, that most physical methods of treatment may improve the affective state but seem to have little or no effect on the unreality feelings. Psychotherapy and analytical methods, of course, have been used extensively; but in stubborn cases show little result. We have attempted an evaluation of results and have classified them according to the responses to convulsion treatment, continuous narcosis, benzedrine, epanutin, vasodilators and abreaction techniques especially with the use of ether, or a combination of carbiazol and ether. On one case Dr. Dalton Sands has had a prefrontal leucotomy performed. Psychotherapy has been used in all cases in conjunction with the physical methods employed.

E.C.T.—39 cases have been treated with a course of electro-shock therapy. This is a treatment commonly used, and it is important for the results to be carefully assessed. The number of treatments given varied from three to fourteen. One of the cases states his depersonalization started after a course of E.C.T. Of the remaining 38 cases only 2 lost their depersonalization, 4 were improved, 1 was temporarily improved, there was no change in 22 cases, and 10 patients stated they were worse. Thus, 32 out of the 39 patients were unchanged or worse after the treatment. Of the 32, 5 were less depressed, 10 slightly improved, and 17 remained the same. Of those that recovered or were much improved, 2 were post-puerperal, 2 were recurrent depressives, and 2 were hysterics with depression.

There is, therefore, little or no place for the use of E.C.T. in the treatment of depersonalization where it is a clinical entity. The treatment is of value for endogenous depressions, but in such cases it is the depression which is relieved and the depersonalization clears up with it.

Continuous narcosis.—15 cases had a full course of continuous narcosis with sodium amytal and paraldehyde. 7 showed no change, 4 appeared worse, and 3 were relieved of their tension with no change in depersonalization. One patient recovered. He was a case of recent onset with marked obsessional and anxiety features. The results on the whole are poor.

Benzedrine and epanutin.—39 cases had a course of treatment with benzedrine 10 to 20 mg. daily. 27 showed no change. 10 cases were improved, generally slightly and only in their affect; one was much improved, but there was a probability that epilepsy complicated this illness, and another case showed improvement in derealization but not in depersonalization. Epanutin in increasing doses was tried with 23 patients, 18 without effect and 5 showed slight improvement. An epileptic patient had her fits controlled by benzedrine and epanutin, but she had a sudden onset of depersonalization when under treatment.

Vasodilators.—These had little or no effect. 13 cases were treated with 50 to 100 mg. t.d.s. of nicotinic acid for weeks without effect. Intravenous injections of 10 c.c. Afenil (CaCl₂-urea) were given daily to 7 patients for a fortnight. There was a slight relief of anxiety in 2 cases, and no change in the remainder.

Ether abreaction ...	14	4	7	3	0

Ether abreaction.—It occurred to Dr. William Sargant and myself [45] that abreaction under ether as a means of excitation might be attempted in the group.

unreality feelings appear worse, it is possible that the depression in its intense form has masked the depersonalization to some extent. Occasionally unreality feelings follow E.C.T. Janet [49] suggested many years ago that in the treatment of depersonalization, excitation is required to raise what he regarded as the lowered degree of consciousness. It is therefore interesting to point out the few successful results with extreme psychological stimulation under ether. This has only been done in a few cases and it appears necessary for a good result to have a lively affect and anxiety. The apathetic, dull or depressed patient responds with the utmost difficulty or not at all.

As Mayer-Gross pointed out, in discussing the mechanism of depersonalization, numerous theories advanced in the past are based on selected facts, and none satisfactorily include all facts. Thus, the following have all been invoked as causes of depersonalization: a "sinking in" of consciousness, a disturbance in temporal-spatial experience, an experience of the loss of volition. Or again a defence against reality, a shift in libido, or an investment of numerous phantom figures with insufficient ego libido in childhood. Finally disturbances at the neuro-physiological level, or disturbance of consciousness at its highest functional level, due to faulty integration and a generalized cerebral cortical dysfunction.

We know the following definite facts about the condition which may throw some light on its mechanism or aetiology.

The positive findings are:

The onset is practically always sudden.

Most typically the onset occurs in adolescence or early maturity.

It occurs as a symptom in a very wide range of psychiatric disorders.

It can occur in normal people as a fleeting experience, for example in fatigue, after anaesthetics, and experimentally during mescaline intoxication.

It is a reversible condition, cases can recover completely and spontaneously.

There is a significant relationship to migraine and to obsessional traits in our cases.

The onset is significantly related to relaxation following intense or prolonged stimulation, psychological or physical.

The condition may be relieved by stimulation.

The symptom can be experienced in any psychological field whether cognitive, affective or conative.

There is a distinct tendency for the symptom to occur in the more intelligent individual.

There is also a tendency for the disturbance to occur in emotionally immature subjects.

There is a high incidence of unsatisfactory parental-child relationship.

There is a higher incidence of non-specific mild abnormality in the E.E.G.s of this group than in any other groups except deteriorated cases.

The negative findings are:

It is not a disorder of visual perception.

It cannot be accounted for in neurological terms by any known focal lesion.

There is no specific relationship with anatomical disease of the brain.

There is a relative absence of olfactory, gustatory, or auditory derealization.

It is extremely rare in children.

It is practically never found in paranoia.

Since the experience can occur in almost anyone under certain conditions, just as a convulsion can, a preformed functional pattern must be present. In those instances where the experience occurs as a significant symptom, there is evidence of a constellation of constitutional deviations. These include obsessional personality, migraine, mild non-specific cerebral dysrhythmia, a specific age of onset, and relative intellectual superiority. Psychologically the patients show themselves as sensitive to the stresses of the child-parent relationship, emotionally immature and introverted. In such individuals, the symptom has a sudden onset, is curiously related to the relaxation following stress, and tends to respond to stimulation of various types. The mechanism of symptom-formation cannot be adequately considered in either physiological or psychological terms alone, nor can any single theory related to partial function be accepted.

become active, regained former interests and affection towards the family and no longer complains of depersonalization. Recently two further long-standing and intractable cases of depersonalization have shown marked benefit after leucotomy operation. The response to leucotomy has been promising but very few cases have so far been done and the response needs further assessment.

DISCUSSION

Our aim in this paper is to make a contribution towards the clinical, diagnostic, and prognostic features of depersonalization, the effects of treatment, and to the discussion of the mechanism involved in the production of this syndrome. One of our difficulties has been the description of what we mean by depersonalization. Since the mechanism is not known, the definition can only be descriptive. Short definitions can only be insufficient, and a complete one would include aspects to which attention has been drawn by many different workers. However, the experience is distressing and seems to be essentially one of unreality; the world feels unreal; the subject feels he is unreal, totally or partially; the symptom never seems to have a delusional quality in the type of case discussed in this paper. The patients have insight. They do not say "I am unreal" but "I feel I am not real, although I know I am." When they speak of a change in their personality, they seem always to refer to a sense of loss. The state bears no resemblance to the personality changes after concussion or encephalitis. The condition can occur in the early stages of all neurosis and psychosis and in some organic conditions but, as Haug [47] pointed out, it is practically absent in paranoia. It is rare in children and senile states. The form of the illness, such as depression or schizophrenia, will determine the quality of the experiences, for example, hallucinations based on depersonalization. Later in a progressive psychosis the symptom is lost, for instance it is lost in the stage of deterioration in schizophrenia. The question thus arises whether depersonalization depends on an intact affect. But it appears that there is a group defined by this paper and with which this paper deals, in which depersonalization exists almost alone and is a clinical entity. This has been called the depersonalization syndrome. Is this condition dependent on an unknown pathophysiological process? and, in this group, is the depersonalization related specifically to such process, or is the pattern determined by genetic or constitutional factors? If depersonalization is dependent on an abnormal brain state it is clear that this group constitutes the obvious material for investigation.

Clinically, the condition is commoner than is generally believed. Depersonalization is the fundamental experience and when it occurs as the predominant and presenting symptom, it has an obsessional quality. A sudden onset is often not described but is vividly remembered if recalled. There is a tendency for the patient to refer to the sudden onset as a "collapse" without further elaboration. Usually severe anxiety and fears follow it for some time, hence the frequent complaints of difficulty in breathing, sinking feeling in the stomach and so on. Depersonalization may easily be missed. Difficulties in diagnosis arise when the symptom causes marked anxiety and depression. The difficulty in describing the symptom, the perplexity to which it gives rise, and the fear of being regarded as insane, result in one or other somatic symptoms being presented, such as giddiness, pains in the head, faints, or fatigue. We have seen patients who have attended hospital for some time regarded as suffering from obsessional neurosis with anxiety in which depersonalization has passed unnoticed. Palmer [48], in discussing acute anxiety attacks in the obsessional group, says "the emphasis is laid on the psychic components, especially the unreality, of the anxiety attack" and that "a sense of unreality which may show itself as depersonalization or derealization, or both, may follow or replace, or constitute the most prominent symptom of the attack following the intense fear". We are stressing the depersonalization, and suggest that it may precede the anxiety. In some obsessional neurotics unreality feelings come and go. Occasionally apparent recurrent attacks of depersonalization prove to be intensifications of the symptom which has persisted throughout in a less intense form and has been accepted by the patient. What might be called primary idiopathic depersonalization starts suddenly in adolescence and may last many years. Generally those cases in our group which have lasted many years with little affective disturbance are those which have begun in adolescence. Clinically, it is found that the more primary the depersonalization, the more unvarying and unyielding it is. One of the reasons the condition is found comparatively frequently in an out-patient department is that the disability accompanying the symptom is mild though persistent. It is important to recognize the presence of depersonalization because of its prognostic significance and its resistance to treatment.

The response to treatment has already been fully discussed. It is largely of a negative character. In those cases in which convulsion therapy relieves the depression but the

unreality feelings appear worse, it is possible that the depression in its intense form has masked the depersonalization to some extent. Occasionally unreality feelings follow E.C.T. Janet [49] suggested many years ago that in the treatment of depersonalization, excitation is required to raise what he regarded as the lowered degree of consciousness. It is therefore interesting to point out the few successful results with extreme psychological stimulation under ether. This has only been done in a few cases and it appears necessary for a good result to have a lively affect and anxiety. The apathetic, dull or depressed patient responds with the utmost difficulty or not at all.

As Mayer-Gross pointed out, in discussing the mechanism of depersonalization, numerous theories advanced in the past are based on selected facts, and none satisfactorily include all facts. Thus, the following have all been invoked as causes of depersonalization: a "sinking in" of consciousness, a disturbance in temporal-spatial experience, an experience of the loss of volition. Or again a defence against reality, a shift in libido, or an investment of numerous phantom figures with insufficient ego libido in childhood. Finally disturbances at the neuro-physiological level, or disturbance of consciousness at its highest functional level, due to faulty integration and a generalized cerebral cortical dysfunction.

We know the following definite facts about the condition which may throw some light on its mechanism or aetiology.

The positive findings are:

The onset is practically always sudden.

Most typically the onset occurs in adolescence or early maturity.

It occurs as a symptom in a very wide range of psychiatric disorders.

It can occur in normal people as a fleeting experience, for example in fatigue, after anaesthetics, and experimentally during mescaline intoxication.

It is a reversible condition, cases can recover completely and spontaneously.

There is a significant relationship to migraine and to obsessional traits in our cases.

The onset is significantly related to relaxation following intense or prolonged stimulation, psychological or physical.

The condition may be relieved by stimulation.

The symptom can be experienced in any psychological field whether cognitive, affective or conative.

There is a distinct tendency for the symptom to occur in the more intelligent individual.

There is also a tendency for the disturbance to occur in emotionally immature subjects.

There is a high incidence of unsatisfactory parental-child relationship.

There is a higher incidence of non-specific mild abnormality in the E.E.G.s of this group than in any other groups except deteriorated cases.

The negative findings are:

It is not a disorder of visual perception.

It cannot be accounted for in neurological terms by any known focal lesion.

There is no specific relationship with anatomical disease of the brain.

There is a relative absence of olfactory, gustatory, or auditory derealization.

It is extremely rare in children.

It is practically never found in paranoia.

Since the experience can occur in almost anyone under certain conditions, just as a convulsion can, a preformed functional pattern must be present. In those instances where the experience occurs as a significant symptom, there is evidence of a constellation of constitutional deviations. These include obsessional personality, migraine, mild non-specific cerebral dysrhythmia, a specific age of onset, and relative intellectual superiority. Psychologically the patients show themselves as sensitive to the stresses of the child-parent relationship, emotionally immature and introverted. In such individuals, the symptom has a sudden onset, is curiously related to the relaxation following stress, and tends to respond to stimulation of various types. The mechanism of symptom-formation cannot be adequately considered in either physiological or psychological terms alone, nor can any single theory related to partial function be accepted.

Dr. W. Mayer-Gross: Dr. Shorvon's interesting clinical study of depersonalization is based on a larger number of patients than any one observer has collected before. Nevertheless, I doubt if his material covers the whole range of clinical pictures in which depersonalization occurs as the leading symptom. While obsessional personalities are preponderant among his cases, he apparently included only a few subjects of cyclothymic temperament. In the latter the symptom is frequent, in fact one-third of my own patients were of this type. It seems debatable if the excess of obsessionals does not account for Dr. Shorvon's findings of unsatisfactory child-parent relationship, and also for some of his results in the Rorschach test. The onset of depersonalization in a state of relaxation after exertion is in good accord with its occurrence in normal fatigue and exhaustion. Relief of the symptom through excitation and mental effort corresponds to the relief of other psychoneurotic symptoms like stammering and phobias in situations of excitement. The results of experimental approach applied for the first time in such patients were disappointing, but not conclusive. Less conventional experimental methods should be tried and may have different results, especially as the abnormal brain potentials seem to point at a distinctive functional disturbance. Finally, I find it difficult to agree with Dr. Shorvon's suggestion of "Primary Idiopathic Depersonalization" as a disease entity, considering the present provisional state of psychiatric classification. We already know of a number of constitutional and incidental factors as well as illnesses on which the presence of the symptom depends. The few cases in which none of these factors is found hardly justify the claim for a special class of disease.

Penicillin Concentration in the Blood and Milk of Bovines

By GEORGE SLAVIN

THE use of penicillin in animal diseases will presumably follow similar lines to those in man but with the compounds at present available and the fact that animals are rarely given hospital treatment, its scope will be more restricted.

GENERAL TREATMENT

We have tried this in cows suffering from low-grade mastitis which had resisted penicillin treatment by direct injection into the udder. The first cow was excreting a Group C streptococcus and was given 128,000 units of sodium penicillin i.m. every three hours for twenty-four hours. With the methods available for the estimation of penicillin in milk none could be detected but the infection suddenly disappeared. The highest blood level reached was approximately $\frac{1}{4}$ unit per c.c. A second cow, which was excreting *Str. agalactiae*, *Str. uberis* and *C. pyogenes*, was given 114,000 units in the same way for the same period, but the infection persisted. The highest blood level reached was again about $\frac{1}{4}$ unit per c.c. This second cow might have responded to a longer course of injections.

The blood levels in these cows seemed to follow the same lines as has been found in man. To get a complete picture a normal cow was given a single injection of 200,000 units of calcium penicillin i.m. and blood samples were collected every five minutes up to 40 minutes, then at 50 minutes, 60 minutes, 133 minutes, 170 minutes, 210 minutes and 240 minutes. The blood levels are shown in fig. 1. The highest level was at 5 minutes with a steady fall until 20 minutes; from then until 60 minutes there was some variation and the level then resumed its steady fall until penicillin could no longer be detected

FIG. 1.—Blood levels of penicillin after a single injection of 200,000 units of calcium penicillin intramuscularly.

at 240 minutes. The two points at 133 and 138 minutes were inserted as a test of the accuracy of the method of estimation.

As it is obviously impossible to use three-hourly injections in practice, the use of oily suspensions was investigated. It was found that 1 mega unit of penicillin in 4% beeswax-arachis oil every twelve hours gave satisfactory blood levels, showing that about ten times the dose given in water was required in order to produce the same blood level. These oily suspensions were injected subcutaneously, mostly at the side of the neck, in order to avoid muscle lesions which might lead to condemnation of part of the carcass. The calcium penicillin used was of low potency and the minimum volume of the injection was about 10 c.c. The inoculum caused a considerable reaction which will, we believe, disappear in time.

Dr. W. Mayer-Gross: Dr. Shorvon's interesting clinical study of depersonalization is based on a larger number of patients than any one observer has collected before. Nevertheless, I doubt if his material covers the whole range of clinical pictures in which depersonalization occurs as the leading symptom. While obsessional personalities are preponderant among his cases, he apparently included only a few subjects of cyclothymic temperament. In the latter the symptom is frequent, in fact one-third of my own patients were of this type. It seems debatable if the excess of obsessionalism does not account for Dr. Shorvon's findings of unsatisfactory child-parent relationship, and also for some of his results in the Rorschach test. The onset of depersonalization in a state of relaxation after exertion is in good accord with its occurrence in normal fatigue and exhaustion. Relief of the symptom through excitation and mental effort corresponds to the relief of other psychoneurotic symptoms like stammering and phobias in situations of excitement. The results of experimental approach applied for the first time in such patients were disappointing, but not conclusive. Less conventional experimental methods should be tried and may have different results, especially as the abnormal brain potentials seem to point at a distinctive functional disturbance. Finally, I find it difficult to agree with Dr. Shorvon's suggestion of "Primary Idiopathic Depersonalization" as a disease entity, considering the present provisional state of psychiatric classification. We already know of a number of constitutional and incidental factors as well as illnesses on which the presence of the symptom depends. The few cases in which none of these factors is found hardly justify the claim for a special class of disease.

Milk.—Milks were titrated against a standard penicillin on a large double layer blood agar plate using a Group A streptococcus as test organism. The plate takes 48 tests in holes punched through the upper layer. The method is sensitive down to 0.07 unit and with care it will detect as little as 0.031 unit. The plate is easy to set up and a large number of estimations can be done quickly.

Lady Florey: Penicillin concentrations in serum after a single intramuscular injection in the cow as shown by Dr. Slavin follow much the same curve as has been found in man. A sharp initial fall is followed by a flattening indicating probably that there is an optimum concentration in the blood-stream below which excretion is minimal. Relatively large doses producing initial high blood concentrations do not therefore produce correspondingly long periods of inhibition.

Two essentials for success in treatment are the full access of the drug to all infected parts and removal of all dead tissue. Local treatment through the udder may sometimes fail when all infected loculi are not reached by this route. Intramuscular treatment may then succeed, for by this means every part of the body is reached to which the circulation has access. Again a small piece of slough infected with *Staph. aureus* is sufficient to prevent complete sterilization of a wound even by extremely high concentrations of penicillin.

The "Drop in slide" method of Dr. N. G. Heatley is less tedious than the slide cell method of Wright for penicillin estimation in serum.

Mr. J. Francis asked whether milking was continued normally when two injections of penicillin were given on consecutive days and whether there was much difference in the susceptibility of different strains of *Str. agalactiae* to penicillin. With regard to the treatment of *C. pyogenes* mastitis he pointed out that the failure of penicillin in this condition was in accord with experimental results with *C. diphtheriae* infection, in which it was known that although penicillin exerted a striking effect on an acute bacteræmic infection it had little or no effect on a chronic local infection. He had found that penicillin had a marked effect on acute *C. pyogenes* infections in mice, but, like others, he had found it ineffective in the treatment of established *C. pyogenes* mastitis.

Mr. K. D. Downham stated that he had treated 50 cows suffering from streptococcal mastitis and that 75% of these animals had been freed from infection, as shown by four subsequent bacteriological examinations of milk samples. He had had no success in the treatment of mastitis due to *C. pyogenes* in dry cows. He described a cow which had suffered from mastitis due to infection with *Str. agalactiae*, whose milk had contained these organisms for eighteen months, and which failed to respond to routine udder infusion with penicillin, but was successfully treated when penicillin was administered in a dosage of 30,000 units in each quarter for two successive days on several occasions with two days' interval after each two days' treatment. This method of intermittent treatment appeared to be of value in the treatment of cows which failed to respond to the routine method of infusion. The cow's milk was found to be free from *Str. agalactiae* organisms when examined on four occasions after this method of treatment.

An Outbreak of Industrial Fluorosis in Cattle

By H. H. GREEN, D.Sc.

It may be recalled that in the "Discussion on Fluorosis in Man and Animals" by this Section in February 1941 the occurrence of severe fluorosis in cattle was described on farms in the vicinity of brickworks in Bedfordshire. The purpose of the present communication is to report a similar occurrence associated with the calcining of ironstone in Lincolnshire. In this process the raw ironstone is mixed with about 7% of its weight of coal and ignited in the open, fresh layers being added to form a smouldering mound, the complete calcining of which occupies several weeks. The weight of the ironstone is so reduced for transport, and the ore rendered sufficiently porous for direct reduction in blast furnaces at distant smelting centres.

During the calcining process smoke drifts on to neighbouring farms, and on the nearest of these an obscure disease of cattle was reported by G. A. Moore, M.R.C.V.S. Samples of urine from affected cases, analysed at Weybridge, at once established a diagnosis by revealing 26 to 69 parts per million of fluorine. Analyses of materials collected during a visit to the area showed 1,200 p.p.m. fluorine in the ironstone itself and 100 to 180 p.p.m. in the various types of coal used. The calcined ore contained only 300 p.p.m., thus revealing a loss of three-quarters of the original fluorine or about four-fifths if loss of weight be allowed for. Imitation of the calcining process in the laboratory showed approximately 90% loss of fluorine at controlled muffle temperature of 850° C., but negligible loss at 600° C. It seems probable that the fluorine comes off as silicon fluoride which, reacting with atmospheric moisture and ammonia from the coal, condenses on the smoke particles as ammonium fluoride and silicofluoride and drifts on to the pastures. Samples of water from the affected farm showed only 0.5 p.p.m. fluorine but grass samples within a few hundred yards of the burning mounds showed over 2,000 p.p.m. on the dry matter. A straw stack about half a mile away showed 490 p.p.m. on the exterior and 70 p.p.m. in the interior. The danger zone has not yet been mapped out but it is not likely to exceed a radius of 2 miles.

LOCAL TREATMENT

Local treatment has been tested on a fairly large scale during the last year but has been confined entirely to mastitis. Considerable success has followed its use in streptococcal mastitis, somewhat less success in staphylococcal mastitis, and so far it has failed in *C. pyogenes* infection although this organism is sensitive to penicillin.

A solution of penicillin in about 50 c.c. of water is injected through the teat canal. Various doses have been tried but the most practicable and successful method is two injections of 100,000 units at twenty-four-hour intervals.

An extensive series of tests was made to follow the fate of the injected penicillin and the concentration in the udder secretion is seen in Tables I to IV.

TABLE I.—RESULTS IN 5 COWS GIVEN 20,000 UNITS PER QUARTER 24 HOURS PREVIOUSLY.

Cow	Qtr.	Yield in lb.	pH	Units of penicillin per c.c.
587	LF	0.75	7.33	0.36

METHODS OF ESTIMATION

Blood.—This was carried out mostly by the slide cell method using either the "Oxford" staphylococcus or a Group A streptococcus, the latter being a very sensitive organism. Unfortunately slide cells are tedious to prepare. We have also tried capillary tubes but the method is less sensitive and we have not had the same degree of success as with slide cells. In both methods the margin of error is large. Dilution methods in broth using the "Oxford" staphylococcus are less laborious and we believe them to be considerably more accurate. The degree of inhibition is read against a standard curve. We have been able to detect about 1/1000 of a unit by this method. To avoid the necessity for large volumes of blood the tests are read in tubes similar to those used for standardizing vaccines against the Brown opacity scale. We prepared our own tubes because the commercially produced ones showed large differences in the glass.

Milk.—Milks were titrated against a standard penicillin on a large double layer blood agar plate using a Group A streptococcus as test organism. The plate takes 48 tests in holes punched through the upper layer. The method is sensitive down to 0.07 unit and with care it will detect as little as 0.031 unit. The plate is easy to set up and a large number of estimations can be done quickly.

Lady Florey: Penicillin concentrations in serum after a single intramuscular injection in the cow as shown by Dr. Slavin follow much the same curve as has been found in man. A sharp initial fall is followed by a flattening indicating probably that there is an optimum concentration in the blood-stream below which excretion is minimal. Relatively large doses producing initial high blood concentrations do not therefore produce correspondingly long periods of inhibition.

Two essentials for success in treatment are the full access of the drug to all infected parts and removal of all dead tissue. Local treatment through the udder may sometimes fail when all infected loculi are not reached by this route. Intramuscular treatment may then succeed, for by this means every part of the body is reached to which the circulation has access. Again a small piece of slough infected with *Staph. aureus* is sufficient to prevent complete sterilization of a wound even by extremely high concentrations of penicillin.

The "Drop in slide" method of Dr. N. G. Heatley is less tedious than the slide cell method of Wright for penicillin estimation in serum.

Mr. J. Francis asked whether milking was continued normally when two injections of penicillin were given on consecutive days and whether there was much difference in the susceptibility of different strains of *Str. agalactiae* to penicillin. With regard to the treatment of *C. pyogenes* mastitis he pointed out that the failure of penicillin in this condition was in accord with experimental results with *C. diphtheriae* infection, in which it was known that although penicillin exerted a striking effect on an acute bacteræmic infection it had little or no effect on a chronic local infection. He had found that penicillin had a marked effect on acute *C. pyogenes* infections in mice, but, like others, he had found it ineffective in the treatment of established *C. pyogenes* mastitis.

Mr. K. D. Downham stated that he had treated 50 cows suffering from streptococcal mastitis and that 75% of these animals had been freed from infection, as shown by four subsequent bacteriological examinations of milk samples. He had had no success in the treatment of mastitis due to *C. pyogenes* in dry cows. He described a cow which had suffered from mastitis due to infection with *Str. agalactiae*, whose milk had contained these organisms for eighteen months, and which failed to respond to routine udder infusion with penicillin, but was successfully treated when penicillin was administered in a dosage of 30,000 units in each quarter for two successive days on several occasions with two days' interval after each two days' treatment. This method of intermittent treatment appeared to be of value in the treatment of cows which failed to respond to the routine method of infusion. The cow's milk was found to be free from *Str. agalactiae* organisms when examined on four occasions after this method of treatment.

An Outbreak of Industrial Fluorosis in Cattle

By H. H. GREEN, D.Sc.

It may be recalled that in the "Discussion on Fluorosis in Man and Animals" by this Section in February 1941¹ the occurrence of severe fluorosis in cattle was described on farms in the vicinity of brickworks in Bedfordshire. The purpose of the present communication is to report a similar occurrence associated with the calcining of ironstone in Lincolnshire. In this process the raw ironstone is mixed with about 7% of its weight of coal and ignited in the open, fresh layers being added to form a smouldering mound, the complete calcining of which occupies several weeks. The weight of the ironstone is so reduced for transport, and the ore rendered sufficiently porous for direct reduction in blast furnaces at distant smelting centres.

During the calcining process smoke drifts on to neighbouring farms, and on the nearest of these an obscure disease of cattle was reported by G. A. Moore, M.R.C.V.S. Samples of urine from affected cases, analysed at Weybridge, at once established a diagnosis by revealing 26 to 69 parts per million of fluorine. Analyses of materials collected during a visit to the area showed 1,200 p.p.m. fluorine in the ironstone itself and 100 to 180 p.p.m. in the various types of coal used. The calcined ore contained only 300 p.p.m., thus revealing a loss of three-quarters of the original fluorine or about four-fifths if loss of weight be allowed for. Imitation of the calcining process in the laboratory showed approximately 90% loss of fluorine at controlled muffle temperature of 850° C., but negligible loss at 600° C. It seems probable that the fluorine comes off as silicon fluoride which, reacting with atmospheric moisture and ammonia from the coal, condenses on the smoke particles as ammonium fluoride and silicofluoride and drifts on to the pastures. Samples of water from the affected farm showed only 0.5 p.p.m. fluorine but grass samples within a few hundred yards of the burning mounds showed over 2,000 p.p.m. on the dry matter. A straw stack about half a mile away showed 490 p.p.m. on the exterior and 70 p.p.m. in the interior. The danger zone has not yet been mapped out but it is not likely to exceed a radius of 2 miles.

Cattle on the nearest farm were stunted and lame and the owner described some of the earlier cases as having to be destroyed after "crawling on their knees". Two cases have been purchased for post-mortem study by F. Blakemore at Cambridge and will doubtless show lesions similar to those described in 1941.

The human family on the same farm is a large one and urine samples of 9 people showed from 1.3 p.p.m. to 4.2 p.p.m. fluorine, averaging less than one-tenth that of the cattle urines but nevertheless being above normal and far above the value in the drinking water. Surface contamination of green vegetables is suggested as the source. Dr. Dagmar Wilson has been asked to consult with the local M.O.H. with regard to clinical symptoms in the children.

Dr. Dagmar Wilson: Our knowledge of human fluorosis has been considerably extended since fluorine was the subject of discussion by this Section in 1941. Fluorine is now generally recognized as an important trace element in human nutrition which exerts influence at non-toxic as well as at toxic levels.

The incidence of fluorotic lesions probably bears a definite relation to the economic and nutritional status of a community. A small amount of fluorine—under 1.0 p.p.m.—is present in many British water supplies and a lowered incidence of dental caries is found amongst people who have used a drinking water containing 0.5 to 1.0 p.p.m. fluorine for at least the first eight years of life. In the United States fluorination of water supplies is being considered for the partial control of dental caries. Human balance experiments show a close correlation between fluorine in the drinking water and in urine, and the elimination of fluorine is practically complete when the quantity absorbed does not exceed 5 mg. daily.

In human toxic fluorosis acute generalized and local effects are usually accidental. Chronic poisoning in man occurs in two ways, as chronic endemic fluorosis and as an occupational disease. Bone abnormalities and systemic illness, of which gastric derangement is an early sign, may occur when fluorine tolerance levels are exceeded.

Fluorides are being increasingly used in industry and large amounts of fluorine are associated with recent industrial development in this country. Methods for the control of the fluorine evolved are known and are not difficult of application, but the fluorine hazards for factory workers, for their families living near-by, and for other people resident or employed in the neighbourhood, as well as for the animal population, are not sufficiently appreciated.

Dr. Margaret M. Murray: In 1937 when Roholm's book "Fluorine Intoxication" was published and reviewed, my attempts to interest appropriate persons in the possibility of a fluorine hazard to human beings in Great Britain, particularly in the Scottish Highlands, failed. Since then we know of three outbreaks of fluorosis in farm animals and it is significant that in each case it was the effects on grazing animals which brought to light the existence of the fluorine hazard; consideration of the effects on human beings has in each case been secondary.

We owe it to Dr. H. H. Green and his colleagues that the cause of the outbreak in the Marston Valley was discovered and the plans for elimination of the danger were successfully worked out.

At Fort William it was because sheep in the vicinity of the aluminium works did not thrive that an inquiry was made into the question of a hazard to human beings. Examining school children at Inverlochy, which has only 0.2 p.p.m. fluorine in the drinking water and which is situated in the direction of the prevailing wind carrying the fumes from the aluminium works, Dr. Wilson and I found the white mottling of dental fluorosis present even in the temporary teeth. We were, and still are, at a loss to explain what was the source of the fluorine which caused this mottling, particularly of temporary teeth.

Dr. Green's investigations show the fundamental importance and usefulness of the determination of fluorine in urine in the study of fluorine intoxication. These outbreaks of fluorosis in farm animals have also shown that not all animals are similarly affected by the ingestion of toxic amounts of fluorine. In cows the long bones are severely affected, while in the sheep at Fort William, investigated by Professor Boddie of the Royal Dick Veterinary College, Edinburgh, it was the jaw bones which were grossly abnormal and because of this the animals could not obtain food. This is the condition seen in the sheep, goats, camels and horses of the "darmous" region of Morocco. In man it is usually the vertebral column which is first affected and this effect may not be detectable until there has been a long period of exposure. Therefore, in the absence of positive X-ray findings, the only means of testing for the ingestion of fluorine at levels which will ultimately cause these bone changes, is by the determination of fluorine in the urine.

The Chick-Embryo in Chemotherapeutic Research. [Summary]

By JOHN FRANCIS, B.Sc., M.R.C.V.S.

OGSTON (1881) was probably the first to cultivate bacteria in the incubating egg, but with the development of satisfactory culture media his work was forgotten. Goodpasture (1938) reviewed other early work with the chick-embryo and Landauer (1941) published an extensive monograph on the factors which influence the hatchability of eggs. Buddingh and Polk (1939a and b) found that by using embryos of suitable ages and inoculating meningococci by various routes they could produce lesions of septicæmia, sinusitis, pneumonia and meningitis, similar to those found in the natural disease; in addition they showed that immune serum had a protective effect. Following this work a considerable number

of chemotherapeutic experiments have been carried out (Green, 1944; Griefff *et al.*, 1944; Koprowski, 1944; Weil, 1941) but no one has made a systematic study to show how the chick-embryo may be used to demonstrate various types of therapeutic activity. When we began our work with the chick-embryo in 1942 (Francis, 1944) we were particularly interested in bovine mastitis. Because of the great variation in the severity and course of mastitis, associated with *Str. agalactiae*, it is almost impossible to compare the value of a large series of drugs against the natural disease. At that time no one had established an easily reproducible disease in mice with *Str. agalactiae* and we hoped that the chick-embryo would prove a suitable experimental "animal" for selecting drugs useful in the treatment of mastitis. The chick-embryo has been successfully used for this purpose and at the same time we have made observations of more general interest showing how various types of therapeutic activity may be demonstrated.

EXPERIMENTAL

Both the infecting organism and the drug can be inoculated by several different routes and in most of our work we have inoculated bacteria on to the chorio-allantois, and have inoculated drugs by a variety of routes one hour later. It can be seen from the accompanying diagram (fig. 1) that if the drug, as well as the bacteria, is inoculated on to the

FIG. 1.—The relative position of the embryo and its membranes after twelve days' incubation (after Lilly).

chorio-allantois, treatment will resemble local application to a wound or into an infected peritoneum. Inoculation of the drug into the allantois may be compared with intravenous or intramuscular therapy and inoculation into the yolk sac bears some resemblance to oral dosing.

Although we have used *Str. agalactiae* most extensively, similar results would undoubtedly have been obtained with Group A streptococci. We have shown that 0.5 to 1 mg. of proflavine has a marked therapeutic effect when applied on to the chorio-allantois but little or none when inoculated into the allantois or yolk sac. We found the sulphonamide drugs equally potent when they were applied directly on to the chorio-allantois, or inoculated into the allantois or yolk sac. Penicillin was, however, considerably more active when applied on to the chorio-allantois than when given by the other two routes.

The Relative Potencies of Various Drugs against *Str. agalactiae*

We have compared the potencies of 4.4' diamino-diphenyl sulphone (sulphone) and various sulphonamides in a large series of experiments. The results have been statistically analysed and are shown in Table I. It will be seen that sulphapyridine and sulpha-

TABLE I.—THE RELATIVE POTENCIES OF VARIOUS DRUGS AGAINST *STR. AGALACTIAE*.

	Chick-embryo	Intrinsic potency in mouse (for comparison)	In <i>vitro</i> in milk
Sulphanilamide	1	1	1
Sulphapyridine	1.25	1.25	
Sulphadiazine	1.30	2.0	
Sulphamezathine	1.84	1.22	
Sulphathiazole	2.33	1.8	
Sulphone	3.15	3.0	4.8

diazine are only slightly more active than sulphanilamide, but sulphone is just over three times as active; sulphamezathine and sulphathiazole occupy an intermediate position.

We have found that similar doses of the various sulphonamides produce similar blood

Cattle on the nearest farm were stunted and launc and the owner described some of the earlier cases as having to be destroyed after "crawling on their knees". Two cases have been purchased for post-mortem study by F. Blakemore at Cambridge and will doubtless show lesions similar to those described in 1941.

The human family on the same farm is a large one and urine samples of 9 people showed from 1.3 p.p.m. to 4.2 p.p.m. fluorine, averaging less than one-tenth that of the cattle urines but nevertheless being above normal and far above the value in the drinking water. The Chick-Embryo in Chemotherapeutic Research. [Summary]

By JOHN FRANCIS, B.Sc., M.R.C.V.S.

OGSTON (1881) was probably the first to cultivate bacteria in the incubating egg, but with the development of satisfactory culture media his work was forgotten. Goodpasture (1938) reviewed other early work with the chick-embryo and Landauer (1941) published an extensive monograph on the factors which influence the hatchability of eggs. Buddingh and Polk (1939a and b) found that by using embryos of suitable ages and inoculating meningococci by various routes they could produce lesions of septicaemia, sinusitis, pneumonia and meningitis, similar to those found in the natural disease; in addition they showed that immune serum had a protective effect. Following this work a considerable number

in mice with *Str. agalactiae*. The relative potencies of the various drugs against this infection are shown in Table I, after allowance has been made for the different blood-levels produced in the mouse. Again it will be seen that sulphone was the most potent drug but sulphadiazine was relatively more potent than in the chick-embryo.

(3) The potencies of some solubilized derivatives were similar to those of the parent compound but sulphanilamide L.S.F. was inactive in our experiments. The activity of various antiseptics was also compared.

(4) The sulphonamides exerted no effect on the multiplication of *C. pyogenes* in the chick-embryo. Penicillin inhibited multiplication of *C. pyogenes* but we have not been impressed with the therapeutic activity of penicillin in the chick-embryo, and its efficiency in preventing death of embryos inoculated with unfiltered sputum (Rose *et al.*, 1945) may be due to the fact that these workers mixed the sputum with the penicillin before inoculation, thus allowing it to exert a direct bactericidal effect.

(5) In common with some other workers we have found that the results obtained in the chick-embryo are rather less consistent than those obtained in the mouse, but certain types of tests can be carried out which cannot be performed in the mouse, and the chick-embryo is susceptible to a number of infections to which laboratory animals are resistant.

The detailed results on which this paper is based will be submitted for publication elsewhere.

Leishmaniasis in Greece

By B. MALAMOS, M.D., D.T.M.

(From the London School of Hygiene and Tropical Medicine, Department of Parasitology)

HUMAN visceral leishmaniasis, canine leishmaniasis and oriental sore are endemic in Greece and, curiously enough, co-exist in some districts.

New foci of kala azar or human visceral leishmaniasis are constantly being discovered. The widest endemic focus seems to be in Messinia; cases also occur in the Peloponnese in the regions of Argos, Nauplia, Patras, Poros, and the islands of Spetsai and Hydra. The disease is also found in Athens, Piraeus, Salamis, the Ionian Islands, Lamia, Thessaly, Macedonia, and, more especially, in Crete.

Kala azar is, in Greece, predominantly a children's disease, occurring mostly in children between 2 and 4 years of age. It is common to find two or more cases in the same house. The clinical picture is that well known for the Mediterranean type of the disease. The dark pigmentation of the skin, however, did not occur in all of our cases. It is strange that in some villages all the cases showed skin haemorrhages while in neighbouring ones not one with this hemorrhagic diathesis was encountered. For the diagnosis we prefer to demonstrate *L. donovani* by puncture of the spleen or the sternum, using for spleen puncture the Aravantinos syringe (fig. 1). Serological diagnostic methods are not employed to the same extent. For therapeutic purposes we use relatively higher doses of drugs than those used in Eastern Asia.

concentrations in the chick-embryo, so it is not necessary to allow for differences in blood concentration when comparing their potency in this host.

The sodium salts of the sulphonamides, except sulphacetamide, are too irritant for infusion into the udder, but there are a number of soluble derivatives available and we have compared their activity¹ against *Str. agalactiae* infection in a smaller series of experiments.

The following drugs were compared at doses of 5 to 10 mg.:

Sulphacetamide

The E.O.S.* derivative
of sulphone

The E.O.S.* derivative
of sulphanilamide

Sulphanilamide L.S.F. A solution of sulphanilamide lactoside, sodium formaldehydesulphoxylate.

*The abbreviation E.O.S. is not strictly correct but has become established in the literature.

Free sulphanilamide exerted its usual therapeutic activity, but sulphacetamide was about four times less active. The activity of sulphanilamide as the E.O.S. derivative was about the same as that of the free drug, but the L.S.F. derivative had no therapeutic effect in these experiments. The E.O.S. derivative of sulphone again had about the same activity as the free compound. These differences are, no doubt, due to variations in the dissociation of the complex molecules and it appears that sulphanilamide L.S.F. hardly dissociates at all in the chick-embryo.

In another series of experiments in which drugs were inoculated on to the chorio-allantois, acriflavine was slightly more potent than proflavine; 2:7 diamino-acridine, 5 amino-acridine and toluidine blue were slightly less potent. Cetavlon was more potent than acriflavine but this drug is unlikely to be suitable for injection into the udder. Rather surprisingly silver proteinate and a commercial sample of tyrothricin were almost inactive, although they were active *in vitro*.

In addition, we have found that the sulphonamides have little or no action against *C. pyogenes* infection in the chick-embryo, which confirms clinical observations, but penicillin does prevent multiplication of the organism. We have tested about one hundred speculative compounds against this infection, but so far we have not found one likely to be of any great therapeutic value.

During the course of the foregoing experiments we have, at times, had a considerable number of embryos die due to bacterial contamination by Gram-negative organisms. Sixteen strains have been isolated and all but two gave the following biochemical reactions:

Glucose	Saccharose	Maltose	Lactose	Dulcitol	Salicin	Lit. milk	Indol	Gelatine	Motility
—	—	—	—	—	—	Alk.	—	Not liquefied	+

It was concluded that they were of the *alcaligenes-faecalis* type and were due to organisms contaminating the shell. These organisms may have infected the embryo when the shell was opened, but it has been shown that bacteria can penetrate the intact shell (Haines and Moran, 1940).

DISCUSSION AND SUMMARY

(1) From the results obtained it can be seen that if proflavine, the sulphonamides and penicillin had been unknown substances we should have concluded that proflavine was a drug with local therapeutic activity, whereas penicillin and the sulphonamides could probably be used systemically. Further, we should have concluded that the sulphonamides were probably bacteriostatic in their action and did not develop bactericidal properties at high concentrations but that, because penicillin was more active when applied locally, it appeared to have bactericidal as well as bacteriostatic properties. The chick-embryo can, therefore, be used to demonstrate these different types of activity.

(2) Diamino-diphenyl sulphone was more potent than any of the sulphonamide drugs against *Str. agalactiae* infection, being about three times more active than sulphanilamide; it may therefore be valuable for the treatment of mastitis.

The relatively low potency of sulphadiazine in the chick-embryo is rather surprising, but since this work was completed we have been able to produce septicæmia and death

¹All doses were adjusted so that identical amounts of the active drugs, i.e. sulphanilamide or sulphone, were given.

in mice with *Str. agalactiae*. The relative potencies of the various drugs against this infection are shown in Table I, after allowance has been made for the different blood-levels produced in the mouse. Again it will be seen that sulphone was the most potent drug but sulphadiazine was relatively more potent than in the chick-embryo.

(3) The potencies of some solubilized derivatives were similar to those of the parent compound but sulphanilamide L.S.F. was inactive in our experiments. The activity of various antiseptics was also compared.

(4) The sulphonamides exerted no effect on the multiplication of *C. pyogenes* in the chick-embryo. Penicillin inhibited multiplication of *C. pyogenes* but we have not been impressed with the therapeutic activity of penicillin in the chick-embryo, and its efficiency in preventing death of embryos inoculated with unfiltered sputum (Rose *et al.*, 1945) may be due to the fact that these workers mixed the sputum with the penicillin before inoculation, thus allowing it to exert a direct bactericidal effect.

(5) In common with some other workers we have found that the results obtained in the chick-embryo are rather less consistent than those obtained in the mouse, but certain types of tests can be carried out which cannot be performed in the mouse, and the chick-embryo is susceptible to a number of infections to which laboratory animals are resistant.

The detailed results on which this paper is based will be submitted for publication elsewhere.

Leishmaniasis in Greece

By B. MALAMOS, M.D., D.T.M.

(From the London School of Hygiene and Tropical Medicine, Department of Parasitology)

HUMAN visceral leishmaniasis, canine leishmaniasis and oriental sore are endemic in Greece and, curiously enough, co-exist in some districts.

New foci of *kala azar* or human visceral leishmaniasis are constantly being discovered. The widest endemic focus seems to be in Messinia; cases also occur in the Peloponnese in the regions of Argos, Nauplia, Patras, Poros, and the islands of Spetsai and Hydra. The disease is also found in Athens, Piraeus, Salamis, the Ionian Islands, Lamia, Thessaly, Macedonia, and, more especially, in Crete.

Kala azar is, in Greece, predominantly a children's disease, occurring mostly in children between 2 and 4 years of age. It is common to find two or more cases in the same house. The clinical picture is that well known for the Mediterranean type of the disease. The dark pigmentation of the skin, however, did not occur in all of our cases. It is strange that in some villages all the cases showed skin hæmorrhages while in neighbouring ones not one with this hæmorrhagic diathesis was encountered. For the diagnosis we prefer to demonstrate *L. donovani* by puncture of the spleen or the sternum, using for spleen puncture the Aravatinos syringe (fig. 1). Serological diagnostic methods are not employed to the same extent. For therapeutic purposes we use relatively higher doses of drugs than those used in Eastern Asia.

concentrations in the chick-embryo, so it is not necessary to allow for differences in blood concentration when comparing their potency in this host.

The sodium salts of the sulphonamides, except sulphacetamide, are too irritant for infusion into the udder, but there are a number of soluble derivatives available and we have compared their activity¹ against *Str. agalactiae* infection in a smaller series of experiments.

The following drugs were compared at doses of 5 to 10 mg.:

Sulphacetamide

The E.O.S.* derivative
of sulphone

The E.O.S.* derivative
of sulphanilamide

Sulphanilamide L.S.F. A solution of sulphanilamide lactoside, sodium formaldehydesulphoxylate.

*The abbreviation E.O.S. is not strictly correct but has become established in the literature.

Free sulphanilamide exerted its usual therapeutic activity, but sulphacetamide was about four times less active. The activity of sulphanilamide as the E.O.S. derivative was about the same as that of the free drug, but the L.S.F. derivative had no therapeutic effect in these experiments. The E.O.S. derivative of sulphone again had about the same activity as the free compound. These differences are, no doubt, due to variations in the dissociation of the complex molecules and it appears that sulphanilamide L.S.F. hardly dissociates at all in the chick-embryo.

In another series of experiments in which drugs were inoculated on to the chorio-allantois, acriflavine was slightly more potent than proflavine; 2:7 diamino-acridine, 5 amino-acridine and toluidine blue were slightly less potent. Leishmaniasis in Greece

By B. MALAMOS, M.D., D.T.M.

(From the London School of Hygiene and Tropical Medicine, Department of Parasitology)

HUMAN visceral leishmaniasis, canine leishmaniasis and oriental sore are endemic in Greece and, curiously enough, co-exist in some districts.

New foci of *kala azar* or human visceral leishmaniasis are constantly being discovered. The widest endemic focus seems to be in Messinia; cases also occur in the Peloponnese in the regions of Argos, Nauplia, Patras, Poros, and the islands of Spetsai and Hydra. The disease is also found in Athens, Piraeus, Salamis, the Ionian Islands, Lamia, Thessaly, Macedonia, and, more especially, in Crete.

Kala azar is, in Greece, predominantly a children's disease, occurring mostly in children between 2 and 4 years of age. It is common to find two or more cases in the same house. The clinical picture is that well known for the Mediterranean type of the disease. The dark pigmentation of the skin, however, did not occur in all of our cases. It is strange that in some villages all the cases showed skin hæmorrhages while in neighbouring ones not one with this hæmorrhagic diathesis was encountered. For the diagnosis we prefer to demonstrate *L. donovani* by puncture of the spleen or the sternum, using for spleen puncture the Aravintinos syringe (fig. 1). Serological diagnostic methods are not employed to the same extent. For therapeutic purposes we use relatively higher doses of drugs than those used in Eastern Asia.

FIG. 1.—Aravantinos spleen puncture syringe. A, 2 c.c. record syringe. B, Piston. C, Metal leaf. D, Spring. E, Ring for insertion of metal leaf. The mechanism is as follows: On making the puncture the metal leaf is inserted in the ring. At the precise moment of puncturing the spleen pulp, the syringe is withdrawn and the metal leaf is pressed. The piston is automatically withdrawn and there is then enough pulp in the needle to make two or three slides.

FIG. 7.

Oriental sore occurs more particularly in Crete, in the districts of Canea, Rethymion, Candia and also in Lakonia in the Peloponnese. Sporadic cases are found in various other districts of Greece, even in Athens. Outbreaks of oriental sore often take on an epidemic character.

This disease is common to all ages, affecting more particularly the uncovered parts of the body. The lower limbs are seldom affected in adults, but often in children. In some cases only one sore is found, in others a hundred or more can be counted. Many of the fresh sores are not ulcerated and have an acneiform appearance (fig. 2) and diagnosis is only possible by the detection of the parasite, *L. tropica*, in smears obtained from the peripheral regions of the sore (figs. 3 and 4). Various treatments are used for cure but none is absolutely effective. Usually local emetine injections are given, or treatment by mepacrine is used, and in Canea 10% powdered vegetable charcoal in concentrated sulphuric acid is often applied locally (figs. 5 and 6). This form of treatment is employed by the people themselves. In oriental sore regions various other skin diseases are often mistaken as being due to *L. tropica*.

Canine leishmaniasis.—This disease in Greece is very common and skin lesions are not rare in dogs. The infection is due only to the parasite of visceral leishmaniasis and never to *L. tropica*. Canine leishmaniasis is found in all regions in which we find human kala azar. It is very often said that in the same or neighbouring houses a canine case preceded a human infection. The clinical picture in dogs is characterized by emaciation, trichoptosis, eczema furfuraceum, ulceration of the skin and mucous membranes, diarrhetic motions, conjunctivitis and keratitis (fig. 7). Very characteristic are ulcerations at the base of the ear. In our mass examinations with M. Mayer in the Canea region we found 50% of the infected dogs with macroscopically normal appearance. The parasite is found in the internal organs, namely spleen, liver, bone-marrow and intestine. The skin, however, is the tissue which seems to contain the greatest number of parasites. We found *Leishmania*, also, in parts of the skin which macroscopically seemed to be normal.

Canine leishmaniasis is, in Greece, more common than human kala azar and it is the endemic form of *L. donovani* which, normally infecting dogs, attacks human beings. From the examination of dogs the following percentages were established of infected animals; in Athens, Cardamatis 8.15%, Lépine and Bilfinger 11 to 12%; in Piraeus, Cardamatis 7.5%; in Hydra, Lignos 16.6%; in Mani, Caminopetros 16%; and in Canea, Papantonakis 20.5%, Adler, Theodor and Witenberg 10%, M. Mayer and the writer 5.1%. In our mass examinations, out of 666 dogs examined in the Canea region all those infected came from the districts of the town and villages where human kala azar cases were to be found. Not a single dog from Splatzia, where oriental sore is endemic, was found to be infected.

It is obvious that if we want to be successful in preventing the spread of human kala azar, we must direct our campaign first towards the infected dog, the reservoir of the parasite. The best measures to be taken with this object in view were published by Papantonakis in the Greek *Official Gazette*, 1937, No. 79, vol. B.

The mode of transmission of leishmaniasis is important. That this transmission has now been proved to take place through the sandfly is due to the excellent work of Shortt (Director of Dept. of Parasitology, Lond. Sch. Hyg. Trop. Med.). *Phlebotomus perniciosus* is considered to be the vector of human and canine visceral leishmaniasis and our observations have proved that for Greece, *Phl. major* and not *Phl. perniciosus* must be considered as responsible for the transmission of this disease.

The main vector of oriental sore in Greece, on the other hand, is the species *Phl. sergenti* and only occasionally *Phl. papatasi*.

From this general and short survey of the vectors of leishmaniasis, it can be realized that the co-existence of the three forms of leishmaniasis can be explained and is most clearly exemplified in Canea (Crete).

Thus, oriental sore occurs principally in Splatzia, the old Turkish centre of the town. The streets there are very narrow with lack of vegetation. 53% of the collected sandflies were *Phl. sergenti* and 47% *Phl. papatasi*. None of the dogs examined was infected. In contrast to this, in the peripheral regions of the town where the houses are of the bungalow type with small gardens and some vegetation we find human and canine visceral leishmaniasis. 49% of the sandflies examined there were *Phl. major*, 45% *Phl. papatasi* and only 6% *Phl. sergenti*.

It is hoped that by the measures taken against infected dogs, as well as by recent improvements in insecticides we shall soon be able to eradicate these diseases.

A fuller account will appear in the *Tropical Diseases Bulletin*, for January 1947.

[July 31, 1946]

DISCUSSION ON DIGESTION IN THE RUMINANT. [Summarized].

A FILM was shown on "The Function of the Ruminant Stomach."

Dr. P. J. Du Toit introduced the film and the subsequent discussion.

He explained that for some years digestion in the ruminant has been investigated at the Onderstepoort Laboratory, South Africa, the work being in charge of Dr. J. I. Quinn, and that the film was made in order to illustrate some phases of the problems involved. Dr. Du Toit had brought the film over to Europe with him in the hope that it would prove to be of interest and stimulate the investigation of this little-known subject. It was not an account of the work done by the Staff at Onderstepoort, but was rather an account of some of the questions that require to be given consideration by those to whom the nutrition of cattle is important. He regretted that none of the Staff who had dealt with the subject were present to describe their work.

Dr. S. R. Elsden: Before we can consider the problem of ruminant digestion in detail we have to know what in fact is the chemical nature of the substances to be digested. Broadly speaking, the fundamental difference between the diet of herbivores, on the one hand, and that of omnivores and carnivores, on the other, is to be found in the carbohydrate fraction. The carbohydrate fraction of the herbivorous diet can be roughly divided into (a) cellulose, associated with a variable amount of lignin, depending on the nature of the diet; (b) hemicellulose and pentosans; (c) polysaccharides, e.g. starch and fructosan; (d) simple sugars such as glucose and sucrose. The first point I want to make is that we know very little of the chemistry of (a) and (b), particularly (b); and secondly, we know even less of the quantitative distribution of each of the four types in feeding stuffs. Here then is the first of the basic problems which must be tackled before a completed picture of ruminant digestion can be obtained—the study of the precise nature and quantitative distribution of the carbohydrate fractions in feeding stuffs.

The adoption of the herbivorous mode of life may be achieved in one of two ways. Either the animal makes use of what may be termed the normal complement of digestive enzymes—this would involve the consumption of a very large bulk of food; or else it must develop some means of digesting the bulky components of the diet—the insoluble cellulose, the hemicellulose and pentosans—thus cutting down the mass of food needed.

The herbivores have adopted the latter alternative and have made use of digestion, or rather fermentation, by means of micro-organisms. Of the herbivores, the ruminants are the most efficient and they can digest from 50% to 70% of the insoluble material in the diet, depending on nature of the diet.

The next question is what does the ruminant obtain as a result of bacterial digestion? It obtains three groups of substances: (a) Volatile fatty acids; (b) B group of vitamins; (c) micro-organisms. The total amount and fate of each of these three groups is important. At the moment we only have precise data on the first of these groups, the volatile fatty acids. Generally speaking, it is true to say that the volatile fatty acids in the rumen consist of acetic, propionic and butyric acids in the proportion of 70:20:10 respectively. Further, these fatty acids are absorbed into the blood-stream through the wall of the rumen and are metabolized by the animal, only a very small proportion being excreted in the urine. From studies of the rate of absorption, it is possible to state that at least 1/6th of the animal's calorific requirements are obtained in the form of volatile fatty acids. It has also been possible to show that the contracting heart can utilize acetic acid as fast as it consumes glucose; on the other hand, our knowledge of the detailed metabolism of these simple compounds is at the moment fragmentary, and would well repay study. It is also important to note that in the rumen no free reducing sugars can be observed, and 100 grammes of glucose can be added direct to the rumen of the normal animal without causing a rise in blood sugar; instead the glucose is fermented very rapidly in the rumen and is converted to volatile fatty acids and lactic acid; while the former are absorbed the latter is not but instead undergoes a further fermentation to volatile fatty acids.

Our knowledge of the production of the B group of vitamins in the rumen is not so complete as that of volatile fatty acids. All that can be said at the moment is that the micro-organisms synthesize the B group far in excess of their own requirements and that in this way the quantity of this group of substances available to the animal is increased. In individual cases, a tenfold increase has been observed in the amount of a given vitamin available to the animal, as a result of bacterial action in the rumen. There is great

scope for further study here and the application of the new methods of microbiological assay now being developed should yield valuable results.

The precise value to the animal of the micro-organisms, apart from their action as agents of digestion, is a matter of conjecture. We have no knowledge of the total weight of micro-organisms produced *per diem*. There is ample evidence in support of the view that part at least of the protein of the diet can be replaced by simple nitrogenous compounds such as ammonium sulphate or chloride, or urea, implying that the micro-flora can make use of these simple compounds in the synthesis of protein which is subsequently utilized by the animal; or, in other words, bacterial and protozoal protein is digested by the animal lower down the alimentary canal. But we have no quantitative data as to the nutritional value of the micro-organisms *per se*, because we do not know the rate of production. Until this data is obtained, it is idle to speculate in any save qualitative terms. This then is a problem of major importance. It is also pertinent to remark that we do not know what happens to the protein of the diet, whether it is converted into bacterial and protozoal protein, or whether it is hydrolysed to amino acids which are absorbed or fermented. The whole problem of protein digestion in the rumen is shrouded in mystery.

The next problem is the nature of the flora and the analysis of it. What are the functional organisms present? That is to say, what are the organisms which are playing an active part in the digestive processes occurring in the rumen, as opposed to those which may be called contaminants? I suspect that, given enough patience, it would be possible to isolate species of almost every family known. It is not sufficient, therefore, to isolate organisms from the rumen; an isolation by itself tells us nothing, unless it can be shown that the organism is playing an active part in digestion. If this rule is not obeyed, an isolation by itself becomes merely an exercise in micro-biological technique rather than a contribution to the study of ruminant digestion. This calls for the closest co-operation between the micro-biologist and the biochemist. So far, only two organisms have been isolated which obey these criteria, an iodophile coccus, and members of the genus *Propionic bacterium*.

A second feature of the microbial population of the rumen is the constancy of its products no matter what the diet, and, at the same time, the dependence of the population on the nature of the diet. It can be readily observed that certain changes in the population occur when the diet is changed. These observations have been made by direct microscopic examination. It may well be that the fundamental organisms do not change, and that such changes as are observed are of little importance. But, none the less, the changes are very marked; on one diet rich in sugars, e.g. mangolds, very large numbers of a pseudo-yeast can be seen; change to a starchy diet, and the yeasts disappear and in their place are iodophile cocci. These observations raise the following question: what are the factors concerned in maintaining a constant population and how does the population protect itself, from the animal's point of view, against invasion by harmful organisms? This brings us down to the necessity for a study of the principles of bacterial ecology. For too long now have bacteriologists been content to isolate organisms in pure culture, neglecting the very important fact that in nature one finds mixed populations rather than pure cultures. Such studies applied to the rumen, would yield results of value and put on to a rational basis the well-known observation that dramatic changes in the diet of ruminants upset the animal.

In conclusion, I wish to emphasize that such work as has been done on ruminant digestion is only a start; there is a great need for chemists, physiologists, biochemists and microbiologists to take up the study of the digestive processes of the ruminants, which after all form our most important group of domestic animals.

Dr. A. T. Phillipson: Fermentation, as a means of digestion, is not confined to ruminants; other animals such as the horse, pig, rabbit and rat are known to produce the same fatty acids in their large intestines as those produced by bacterial fermentation in the rumen. In addition the dog can now be added to the list for acetic and propionic acids are now known to be present in the digesta of the colon in concentrations which compare with the concentrations found in the large intestines of other animals. Alimentary fermentation, therefore, is quite a widespread process but its importance relative to digestion by enzymes of glandular origin varies in different species and, as far as one can tell at present, it is in the ruminant that it assumes the greatest dimensions.

One remarkable feature of digestion in the rumen is that bacteria that are detrimental to the host do not flourish in spite of the fact that conditions for anaerobic bacterial growth are ideal. One is forced to ask the question whether this state of affairs always exists or whether it is possible that under certain circumstances, such as a change of

[July 31, 1946]

DISCUSSION ON DIGESTION IN THE RUMINANT. [Summarized].

A FILM was shown on "The Function of the Ruminant Stomach."

Dr. P. J. Du Toit introduced the film and the subsequent discussion.

He explained that for some years digestion in the ruminant has been investigated at the Onderstepoort Laboratory, South Africa, the work being in charge of Dr. J. I. Quinn, and that the film was made in order to illustrate some phases of the problems involved. Dr. Du Toit had brought the film over to Europe with him in the hope that it would prove to be of interest and stimulate the investigation of this little-known subject. It was not an account of the work done by the Staff at Onderstepoort, but was rather an account of some of the questions that require to be given consideration by those to whom the nutrition of cattle is important. He regretted that none of the Staff who had dealt with the subject were present to describe their work.

Dr. S. R. Elsden: Before we can consider the problem of ruminant digestion in detail we have to know what in fact is the chemical nature of the substances to be digested. Broadly speaking, the fundamental difference between the diet of herbivores, on the one hand, and that of omnivores and carnivores, on the other, is to be found in the carbohydrate fraction. The carbohydrate fraction of the herbivorous diet can be roughly divided into (a) cellulose, associated with a variable amount of lignin, depending on the nature of the diet; (b) hemicellulose and pentosans; (c) polysaccharides, e.g. starch and fructosan; (d) simple sugars such as glucose and sucrose. The first point I want to make is that we know very little of the chemistry of (a) and (b), particularly (b); and secondly, we know even less of the quantitative distribution of each of the four types in feeding stuffs. Here then is the first of the basic problems which must be tackled before a completed picture of ruminant digestion can be obtained—the study of the precise nature and quantitative distribution of the carbohydrate fractions in feeding stuffs.

The adoption of the herbivorous mode of life may be achieved in one of two ways. Either the animal makes use of what may be termed the normal complement of digestive enzymes—this would involve the consumption of a very large bulk of food; or else it must develop some means of digesting the bulky components of the diet—the insoluble cellulose, the hemicellulose and pentosans—thus cutting down the mass of food needed.

The herbivores have adopted the latter alternative and have made use of digestion, or rather fermentation, by means of micro-organisms. Of the herbivores, the ruminants are the most efficient and they can digest from 50% to 70% of the insoluble material in the diet, depending on nature of the diet.

The next question is what does the ruminant obtain as a result of bacterial digestion? It obtains three groups of substances: (a) Volatile fatty acids; (b) B group of vitamins; (c) micro-organisms. The total amount and fate of each of these three groups is important. At the moment we only have precise data on the first of these groups, the volatile fatty acids. Generally speaking, it is true to say that the volatile fatty acids in the rumen consist of acetic, propionic and butyric acids in the proportion of 70:20:10 respectively. Further, these fatty acids are absorbed into the blood-stream through the wall of the rumen and are metabolized by the animal, only a very small proportion being excreted in the urine. From studies of the rate of absorption, it is possible to state that at least 1/6th of the animal's calorific requirements are obtained in the form of volatile fatty acids. It has also been possible to show that the contracting heart can utilize acetic acid as fast as it consumes glucose; on the other hand, our knowledge of the detailed metabolism of these simple compounds is at the moment fragmentary, and would well repay study. It is also important to note that in the rumen no free reducing sugars can be observed, and 100 grammes of glucose can be added direct to the rumen of the normal animal without causing a rise in blood sugar; instead the glucose is fermented very rapidly in the rumen and is converted to volatile fatty acids and lactic acid; while the former are absorbed the latter is not but instead undergoes a further fermentation to volatile fatty acids.

Our knowledge of the production of the B group of vitamins in the rumen is not so complete as that of volatile fatty acids. All that can be said at the moment is that the micro-organisms synthesize the B group far in excess of their own requirements and that in this way the quantity of this group of substances available to the animal is increased. In individual cases, a tenfold increase has been observed in the amount of a given vitamin available to the animal, as a result of bacterial action in the rumen. There is great

are abundant in grass so that if the lower fatty acids of the milk of an animal reflect its grass intake the order of species in Hilditch's table would be satisfactorily explained.

The problem of the origin of the lower fatty acids in milk will doubtless be solved when isotopes of C, N and H become available in quantities sufficient for dietary experiments with large animals.

Mr. A. Brownlee: Observations on stall-fed cattle show that these animals follow a fairly regular routine in their rumination habits. After a meal there is usually a period lasting twenty minutes or longer during which the animals do not ruminate. Rumination then commences and continues for a period averaging about twenty-eight minutes. This period is followed by a non-ruminating period averaging about thirty-eight minutes, to be followed by alternate similar periods of rumination and non-rumination until the next feeding time approaches. In a heifer fed strictly twice per day, eleven such ruminating periods were observed to occur between an evening and a morning feed.

During the non-ruminating periods cows swallow saliva at the rate of about $1\frac{1}{2}$ swallows per minute. In a sheep which was destroyed and the abdomen opened without delay, the reticulum was found to be filled with fluid contents in contrast to the more solid contents of the rumen. It would have been interesting to know if this fluid was saliva. Attempts to confirm this observation in slaughterhouse material have so far been unsuccessful.

The following observation was made on cows grazing during daytime and housed at night. At the time of observation most of these animals had been grazing continuously for a period of at least three hours on good aftermath about half eaten down. A number of animals then drank water and almost immediately several of them commenced to ruminate. Most of these stifled the rumination reflex and recommenced grazing.

Dr. F. H. Malpress: Dr. Owen has remarked that the absorption of large quantities of the lower fatty acids from the rumen might be related to the presence of lower fatty acids in large amounts in the butter-fat of ruminants. He may be interested to know that work is already in progress at N.I.R.D., Shinfield, designed to investigate any such relationship. The aim of the initial experiments has been to show whether it is possible to modify the characteristic changes in the fatty acid content of butter-fat, known to attend the starvation of lactating ruminants, by coupling starvation with the intravenous infusion of salts of the lower fatty acids. The work is incomplete and as yet inconclusive, but already there are grounds for believing that such modification is possible and that the mammary gland can utilize circulating fatty acids of this type to some extent in the formation of milk-fat.

Mr. G. N. Gould: My contribution to the discussion will be from the clinical aspect and will deal with the problem of "bloat". Although it has been possible by the use of the ley system markedly to increase productive value of pasturage, problems have arisen of great importance and interest to veterinarians and agriculturists. One of the most important is the tendency to "bloat" which has been frequently responsible for deaths in cattle grazed on leys.

One system of management which is claimed to be valuable in prevention, is for the cattle to be turned on to the leys for a comparatively short period and then removed to a straw yard or bare pasture. This, not infrequently, proves satisfactory but involves not only considerable organization but also labour which is at a minimum on most farms to-day and which, moreover, is expensive.

I have recently had a most interesting experience with a herd of pedigree Jersey cows which tends to demonstrate the possibility of the psychological aspect being worthy of

diet, the stability of the flora is upset and that bacteria detrimental to the host make their appearance in quantity, or alternatively, that organisms which normally produce useful materials elaborate materials harmful to the host, due to change in environment. The condition known as "Bloat" is one instance in which something of this nature may be happening. Death in bloat is attributed to pressure of gas in the rumen impeding either or both the circulation and respiration. There is no experimental proof, however, to show that pressure as such in the rumen will seriously interfere with either of these systems and there is no evidence to show that the pressures that have been recorded in living bloated animals are lethal. Until this question is settled there is good reason to suppose that some other factor is concerned and that bacterial products other than gas are produced and absorbed from the rumen under the influence of the sudden change of diet which occurs when animals are turned on to leguminous pastures. Bloat is only one instance of the conditions which are open to investigation on these lines but it is necessary that more be known of the normal processes of digestion in the rumen before much progress can be made in this direction and for this reason, apart from the nutritional problems involved, the study of digestion, and particularly of the microbiology of the rumen, is important.

Dr. E. C. Owen: I have just completed a review of the literature of ruminant nutrition. I had been looking especially for evidence as to the exact role played by bacteria in digesting cellulose but I found that the chemical evidence on this point was far from satisfactory. Kellner's experiments with cellulose and numerous other more recent observations make it certain that the ruminant digests a considerable proportion of the cellulose it ingests.

Microscopic observation of rumen contents [1] gives circumstantial evidence that certain cocci are cytotoxic while other observations in the living animal show that cellulose digestion in the ruminant was not confined to the rumen. It also occurs in post-abomasal regions of the gut [2]. I agree with Dr. Elsdén that biochemically satisfactory evidence as to the organism or organisms in the rumen which are responsible for the breakdown of cellulose is still lacking. Organisms have been isolated from rumen contents and have been found to be able to break down cellulose, but the conditions under which the breakdown occurs are not comparable to conditions obtaining in the rumen. There is a danger too, that a specific bacterium isolated from the rumen is merely a passenger therein. For this reason microscopically controlled cultures of mixed rumen flora are more likely to reflect the conditions in the rumen than are cultures of isolated bacteria, particularly if plating be used for the isolation. Such objections apply to the work of Pochon [3] whose organism *Plectridium cellulolyticum* was a spore-former isolated by plating. Pochon found it in rumen contents at pH 8, a pH too alkaline to be considered as normal.

Dr. Elsdén has drawn attention to the importance of acetic acid as a product of the fermentation which occurs in the rumen and of which he and his colleagues at Cambridge are making an intensive study [4]. There has recently been a revival of interest in America as to the role of acetic acid in intermediary metabolism. Work with heavy and with radio-isotopes has shown that acetic acid can form both fat and glycogen in the liver and body tissues and that it is an important precursor of cholesterol.

In the rumen acetic acid is formed from carbohydrates such as starch and sugar. It still remains to be shown to what extent cellulose in the rumen is responsible for acetic acid production.

The generation of acetic and other lower fatty acids in the rumen may have a bearing on the origin of the lower fatty acids of milk fat, an outstanding problem in the metabolism of milk secretion. Hilditch [5] has arranged 13 different species of mammals in the order of increasing concentration of lower fatty acids. An examination of this table of species from a biological standpoint is very interesting. It so happens that a carnivore, the dog, heads the list with the lowest value. After the dog come the omnivora, pig, man and mouse. Next come the herbivora, horse, ass and rabbit, while last of all with the greatest values come the ruminants, camel, goat, sheep, buffalo and cow.

It is tempting to suppose that the extent of generation of acetic acid and other simple fatty acids in fermentations due to bacteria inhabiting the gut is responsible for the increase of lower fatty acids in the milk as one passes from the dog to the cow.

Contrary, however, to such a hypothesis is the hypothesis of Hilditch that the lower fatty acids in the milk originate from the unsaturated fatty acids, such as linolenic, which

are abundant in grass so that if the lower fatty acids of the milk of an animal reflect its grass intake the order of species in Hilditch's table would be satisfactorily explained.

The problem of the origin of the lower fatty acids in milk will doubtless be solved when isotopes of C, N and H become available in quantities sufficient for dietary experiments with large animals.

Mr. G. N. Gould: My contribution to the discussion will be from the clinical aspect and will deal with the problem of "bloat". Although it has been possible by the use of the ley system markedly to increase productive value of pasturage, problems have arisen of great importance and interest to veterinarians and agriculturists. One of the most important is the tendency to "bloat" which has been frequently responsible for deaths in cattle grazed on leys.

One system of management which is claimed to be valuable in prevention, is for the cattle to be turned on to the leys for a comparatively short period and then removed to a straw yard or bare pasture. This, not infrequently, proves satisfactory but involves not only considerable organization but also labour which is at a minimum on most farms to-day and which, moreover, is expensive.

I have recently had a most interesting experience with a herd of pedigree Jersey cows which tends to demonstrate the possibility of the psychological aspect being worthy of

consideration. This herd of thirty-six high pedigree cows and heifers, had, from the beginning of April, been grazing on a ley consisting of rye grass, cocksfoot and S.100 clover. When first turned out there was a luxuriant growth with the grasses standing well above the clover. For the first week the herd was grazed for one hour twice daily, and there was no trouble, but it was noticeable that they "skimmed" the surface of the pasture taking mainly the grasses standing above the clover. When they reached the clover the trouble started, and from time to time cows became blown. One was lost—dying within half an hour of the condition being noticed, three-quarters of an hour after the animal had left the pasture and been placed in a practically bare milking yard.

The period of time was then reduced to three-quarters of an hour, but blowing continued to occur with monotonous regularity. In turn other cows in the herd were affected, and it was not uncommon to find anything between nine to fifteen cows in various states of "bloat". The period was gradually reduced until it became twenty minutes' grazing twice daily.

A change on to another re-seeded pasture consisting of S.100 clover, some wild white clover, cocksfoot, rye grass and old pasture grasses, caused exactly the same results, and as the farm was one in which there was no permanent pasture left and little or no hay available, the condition had really become desperate. Hay and straw were provided for the cattle before they went to pasture and at pasture, but they were steadfastly refusing to eat it, and the tendency to "bloat" continued. This had previously proved to be a satisfactory preventive measure on other farms, provided the cows would eat the straw and hay.

In the owner's absence abroad, the management of the herd passed over to me, and on the first night fifteen cows were blown within half an hour of being moved from the ley after twenty minutes' grazing. I decided to move the whole of the cows from the ley and put them in the collecting yard and change them over on to full winter rations of hay and concentrates.

After a period of five days, six cows which had been frequently blown from the period April to June 1, were placed on the re-seeded pasture after giving them access to as much dry food as they would eat, in the way of hay and their usual production ration, following the afternoon milking. They were carefully watched and it was noticeable how greedily they ate with their heads down to pasturage the whole time. At the end of twenty minutes all the cows moved to the gate as if ready to leave the field, but they were left and a watch kept on them during the evening. All six appeared full but showed no evidence of "bloat". After thirty to forty minutes they lay down and ruminated and were left for the night. When they came in for morning milking they received a production ration and a small amount of hay, and were put out again and left until the afternoon milking. They ate less greedily and moved about more, but they came down to the gate at the end of twenty minutes. They were allowed to remain under supervision until the afternoon milking, and no trouble occurred, and the same procedure was followed subsequently.

After three days they gave up the habit of coming down to the gate at the end of twenty minutes, and dispersed themselves over the pasture much more than in the previous three days.

At that time six more cows were introduced and a comparison made in grazing methods. The six new cows showed the same tendency to greedy feeding with their heads down to the ground, and at the end of twenty minutes were waiting at the gate. The same procedure was again successfully followed, and ultimately all the cows in the herd were on the pasture and staying there for twenty-four hours on end, other than for the times they were taken in for milking, and the tendency to "bloat" had disappeared. It took three to four days in all cases for the cows to get over the habit of coming down to the gate as if waiting to be removed from the pasture. It was very noticeable that the cows, when first introduced, ate greedily with their heads down to the pasture all the time, and that they moved very little. Normally a cow will graze and lift its head frequently and move on. At the time of lifting the head, particularly on a luscious pasture, belching is frequently noticed. It would appear that in this particular case a psychological condition had arisen as a result of which the cows assumed the habit of eating as fast as they could in the shortest possible time, due to continued reduction in grazing period, and this was contributing to the tendency to "bloat" to a marked extent.

The change in management enabled the cows to graze full time on pastures which seven to fourteen days previously had been too dangerous to continue to use.

Evidence for a Vascular Mechanism in Ménière's Syndrome

By MILES ATKINSON, M.D., F.R.C.S.

If histamine is injected into the skin, what Lewis called "the triple response" takes place: (1) a raised red area in the skin; (2) the rapid formation of a bleb, and (3) a surrounding area of erythema. This qualitative experiment can be turned into a quantitative test by injecting intradermally a known amount of histamine solution of known strength, and that is the basis of the histamine skin test. The injection, given into the skin of the volar surface of the forearm just below the elbow, consists of 0.05 c.c. of a 1/10,000 solution of histamine calculated in terms of histamine base, not in terms of one of the salts. If this quantity is injected into the forearm there appears within a minute or so in the normal subject a raised red area and, following this, the rapid formation of a yellow bleb surrounded by an area of erythema. That yellow bleb in the normal subject is from 1/4 in. to 1/3 in. across, and the area of erythema surrounding it from 1 in. to 1½ in. in diameter. The reaction remains like that for from five to ten minutes and then begins to fade. In twenty minutes the bleb has faded into the

consideration. This herd of thirty-six high pedigree cows and heifers, had, from the beginning of April, been grazing on a ley consisting of rye grass, cocksfoot and S.100 clover. When first turned out there was a luxuriant growth with the grasses standing well above the clover. For the first week the herd was grazed for one hour twice daily, and there was no trouble, but it was noticeable that they "skimmed" the surface of the pasture taking mainly the grasses standing above the clover. When they reached the clover the trouble started, and from time to time cows became blown. One was lost—dying within half an hour of the condition being noticed, three-quarters of an hour after the animal had left the pasture and been placed in a practically bare milking yard.

The period of time was then reduced to three-quarters of an hour, but blowing continued to occur with monotonous regularity. In turn other cows in the herd were affected, and it was not uncommon to find anything between nine to fifteen cows in various states of "bloat". The period was gradually reduced until it became twenty minutes' grazing twice daily.

A change on to another re-seeded pasture consisting of S.100 clover, some wild white clover, cocksfoot, rye grass and old pasture grasses, caused exactly the same results, and as the farm was one in which there was no permanent pasture left and little or no hay available, the condition had really become desperate. Hay and straw were provided for the cattle before they went to pasture and at pasture, but they were steadfastly refusing to eat it, and the tendency to "bloat" continued. This had previously proved to be a satisfactory preventive measure on other farms, provided the cows would eat the straw and hay.

In the owner's absence abroad, the management of the herd passed over to me, and on the first night fifteen cows were blown within half an hour of being moved from the ley after twenty minutes' grazing. I decided to move the whole of the cows from the ley and put them in the collecting yard and change them over on to full winter rations of hay and concentrates.

After a period of five days, six cows which had been frequently blown from the period April to June 1, were placed on the re-seeded pasture after giving them access to as much dry food as they would eat, in the way of hay and their usual production ration, following the afternoon milking. They were carefully watched and it was noticeable how greedily they ate with their heads down to pasturage the whole time. At the end of twenty minutes all the cows moved to the gate as if ready to leave the field, but they were left and a watch kept on them during the evening. All six appeared full but showed no evidence of "bloat". After thirty to forty minutes they lay down and ruminated and were left for the night. When they came in for morning milking they received a production ration and a small amount of hay, and were put out again and left until the afternoon milking. They ate less greedily and moved about more, but they came down to the gate at the end of twenty minutes. They were allowed to remain under supervision until the afternoon milking, and no trouble occurred, and the same procedure was followed subsequently.

After three days they gave up the habit of coming down to the gate at the end of twenty minutes, and dispersed themselves over the pasture much more than in the previous three days.

At that time six more cows were introduced and a comparison made in grazing methods. The six new cows showed the same tendency to greedy feeding with their heads down to the ground, and at the end of twenty minutes were waiting at the gate. The same procedure was again successfully followed, and ultimately all the cows in the herd were on the pasture and staying there for twenty-four hours on end, other than for the times they were taken in for milking, and the tendency to "bloat" had disappeared. It took three to four days in all cases for the cows to get over the habit of coming down to the gate as if waiting to be removed from the pasture. It was very noticeable that the cows, when first introduced, ate greedily with their heads down to the pasture all the time, and that they moved very little. Normally a cow will graze and lift its head frequently and move on. At the time of lifting the head, particularly on a luscious pasture, belching is frequently noticed. It would appear that in this particular case a psychological condition had arisen as a result of which the cows assumed the habit of eating as fast as they could in the shortest possible time, due to continued reduction in grazing period, and this was contributing to the tendency to "bloat" to a marked extent.

The change in management enabled the cows to graze full time on pastures which seven to fourteen days previously had been too dangerous to continue to use.

Intramuscular injections may have to be continued for many months, as there is, for a long time, danger of relapse unless treatment is continuous.

After showing audiograms of cases, Dr. Miles Atkinson summed up by saying: The histamine skin test divides Ménière patients into two groups: histamine-positive and histamine-negative, the first being a small group and the second large, in the proportion of about 1 to 5 or 6. The histamine-positive group is best treated with histamine desensitization and responds extremely well, so much so that I used to say that to get a positive reaction to histamine was as much a prognosis as a diagnosis. The other, the bigger group, should be treated with vasodilators, of which nicotinic acid has proved in my hands the best. They respond well, and if one is patient and persistent there are very few cases which cannot be got under control by medical treatment.

Mr. V. E. Negus said that he had been interested in histamine and its effects, particularly as regards the nasal aspect of the allergic reaction. The latter was merely a peculiar response of the tissues and could be caused by the breaking down of histidine. If histamine were released, œdema was produced, due to capillary dilatation and the increased permeability of cell walls, with increase of fluid in the tissue spaces. The œdema could be reduced by calcium, or by the driving in of hydrogen ions by ionization. Very often an allergen was not found in typical nasal allergy, nor was it found in cases of chronic nasal œdema. It did not mean that because a skin reaction was not found there was not something at work similar to the allergic reaction, which could produce these changes.

A large number of patients were treated for sinusitis because they had pains in the head and temporal region, and one of the popular methods of treatment was by displacement. Even in the case of such rheumatic affections, œdema of the muscles of the lumbar region, as a result of physical allergy, had been found causing pressure within the muscle sheaths and causing the pain of lumbago.

Dr. John Freeman, who had done a great deal of work on allergic conditions, laid great stress on the factor of response to bacterial growth. In the treatment of many conditions due to organisms the occurrence of secondary allergic effects could be brought about. Many skeletal muscles and joints gave an allergic response, and for his own part he did not see any great difficulty in agreeing with the theory of indirect bacterial causation. Professor Atkinson's interesting talk on hypo-sensitization with histamine seemed to fit in very well with other theories of allergic reactions.

He had recently been interested in seeing an elderly lady who first came to him in 1938 complaining of sudden and almost complete deafness in her right ear. She had no vertigo or signs of hæmorrhage and her labyrinth was well functioning. Various investigations were carried out. About three weeks ago she came again with exactly the same condition in the other ear—sudden deafness with very severe tinnitus, but no vertigo. The cochlea was found to be depressed over all ranges. There was obviously a cochlear deafness. The caloric reactions showed that the labyrinths were both functioning. He got some insight into the condition on reading a paper showing that the changes of Ménière's disease might start in the cochlea. The cochlea might be regarded as a "shock" organ, just as allergists spoke of other organs of the body as shock organs. He gave this lady ammonium chloride to fix salt, and she now wrote to say that she was much better—the tinnitus had diminished until it was tolerable, and so far as the deafness was concerned she was now able to hear the wireless.

He had been interested in seeing a Report on the use of benadryl from the Mayo Clinic. He wondered whether this was likely to be of use in cases of primary aural vertigo.

Ménière's Disease—A Critical Review

By A. J. WRIGHT, F.R.C.S.

SOME nine years ago I first contributed a paper on this subject to this Section (*Proc. R. Soc. Med.*, 1937, 31, 87). Since that time two outstanding advances in our knowledge of Ménière's disease have been achieved in that both the clinical and pathological pictures have been defined and we now regard Ménière's disease as an entity. The fundamental cause of the disease is as yet unproven.

Clinical picture.—(1) Ménière's disease occurs in individuals at all ages and is not obviously associated with any other gross constitutional disturbance.

(2) Two types which perhaps are distinct can be recognized. The more usual one in which the lesion is essentially unilateral, and the less common one in which it is bilateral and approximately equal from the beginning. The latter cases tend to be more rapid in development and more resistant to treatment and remain for further investigation.

(3) The first signs of the disease are usually associated with the cochlea and it may possibly be of significance that this contains the vascular area which is probably in the main responsible for the secretion of endolymph.

(4) As a corollary to this many cases of perceptive deafness are explainable as being the initial stages of the disease and these are I believe usually recognizable.

surrounding erythema and in half an hour or so the whole thing has disappeared save for a little mark at the point of injection which may remain for twenty-four hours. That relates to the histamine-negative or—insensitive subject.

The histamine-positive or sensitive subject gives the same reaction as the normal except that it is much larger. The bleb measures from $\frac{3}{4}$ in. to 1 in. across, sometimes even more, while the surrounding erythema may be as much as 2 in. to $2\frac{1}{2}$ in. across. But the outstanding characteristic is the appearance of a long trailing pseudopodium from 1 in. to $1\frac{1}{2}$ in. in length. This represents a lymphatic made evident by the histamine. There may even be two pseudopodia if two lymphatics are available at the site of injection to be marked out by the histamine.

Between these two extremes of the negative or insensitive and the positive or sensitive there are intermediate stages which require a certain amount of judgment and experience to evaluate.

The treatment of the two groups is quite different, and it is therefore important to form an accurate assessment of the group to which each patient belongs, whether negative or positive. If in doubt, one should undertake a second test with double the dose, using preferably the opposite forearm and leaving an interval of forty-eight hours for the reactionary period. If with that double dose no pseudopodium appears one can be satisfied that the case is histamine-insensitive.

What does this mean? Histamine is a vasodilator substance. If injected intravenously in sufficient dosage a marked flushing of the face occurs. Therefore, when these two classes of cases were discovered, it was assumed that the one that gives the large response, the histamine-positive, does so because it possesses a primary vasodilator mechanism. The other, the histamine-negative group, was assumed to possess a primary vasoconstrictor mechanism. If these assumptions are correct, those patients who give a positive response to histamine should be made worse by vasodilator drugs and better by vasoconstrictor drugs; while in the histamine-negative group precisely the reverse should occur. This is, in fact, what happens.

If a member of the histamine-positive group be given amyl nitrite to inhale, the result may be an attack and, nearly always, at least a vestibular response. The same thing will happen with other vasodilator drugs. Recently a histamine-positive patient was inadvertently given an intravenous injection of 35 mg. of nicotinic acid. A very considerable flush response resulted. About one hour later she had as severe an attack of Ménière's syndrome as she had ever had in her life. That is not an isolated instance; the same result has been observed many times following the mistaken administration of a vasodilator drug to a histamine-positive patient.

In the insensitive group, if the patient is given one of the vasoconstrictors such as ergotamine tartrate or benzedrine it is frequently possible to produce an attack or even a succession of attacks, while the patient can be swung out of an attack sometimes by giving amyl nitrite.

The speaker here showed by means of a diagram the results of treatment in the two groups. Briefly, the histamine-sensitive group had been found to be best treated by histamine-desensitization—gradually increasing doses of histamine given subcutaneously. The results have been very satisfactory. The method is to start with the same dose subcutaneously as was given for testing intracutaneously and gradually work up. Two audiograms were shown demonstrating improvement in hearing with correct treatment, deterioration with incorrect.

The same thing applied to the other histamine-insensitive group, but the other way round—correct treatment, using nicotinic acid as the vasodilator improved the situation, incorrect treatment produced deterioration.

The results in both groups as far as the attacks of vertigo were concerned were very satisfactory, about 80% being relieved or greatly improved. As far as tinnitus was concerned, about 50% are greatly improved; improvement in deafness is unusual, 20% or less.

The treatment of the larger group calls for patience and perseverance on the part both of the patient and the doctor. Our routine is to give nicotinic acid at first intravenously, starting with 25 mg. and increasing by 5 mg. a day until the maximum tolerance is reached somewhere between 50 to 100 mg. daily. After tolerance limit is established the same daily dose is continued intramuscularly and this the patient can be taught to give himself. At the same time, nicotinic acid is given orally in daily dosage of 150 to 300 mg.

Intramuscular injections may have to be continued for many months, as there is, for a long time, danger of relapse unless treatment is continuous.

After showing audiograms of cases, Dr. Milcs Atkinson summed up by saying: The histamine skin test divides Ménière patients into two groups: histamine-positive and histamine-negative, the first being a small group and the second large, in the proportion of about 1 to 5 or 6. The histamine-positive group is best treated with histamine desensitization and responds extremely well, so much so that I used to say that to get a positive reaction to histamine was as much a prognosis as a diagnosis. The other, the bigger group, should be treated with vasodilators, of which nicotinic acid has proved in my hands the best. They respond well, and if one is patient and persistent there are very few cases which cannot be got under control by medical treatment.

Mr. V. E. Negus said that he had been interested in histamine and its effects, particularly as regards the nasal aspect of the allergic reaction. The latter was merely a peculiar response of the tissues and could be caused by the breaking down of histidine. If histamine were released, oedema was produced, due to capillary dilatation and the increased permeability of cell walls, with increase of fluid in the tissue spaces. The oedema could be reduced by calcium, or by the driving in of hydrogen ions by ionization. Very often an allergen was not found in typical nasal allergy, nor was it found in cases of chronic nasal oedema. It did not mean that because a skin reaction was not found there was not something at work similar to the allergic reaction, which could produce these changes.

A large number of patients were treated for sinusitis because they had pains in the head and temporal region, and one of the popular methods of treatment was by displacement. Even in the case of such rheumatic affections, oedema of the muscles of the lumbar region, as a result of physical allergy, had been found causing pressure within the muscle sheaths and causing the pain of lumbago.

Dr. John Freeman, who had done a great deal of work on allergic conditions, laid great stress on the factor of response to bacterial growth. In the treatment of many conditions due to organisms the occurrence of secondary allergic effects could be brought about. Many skeletal muscles and joints gave an allergic response, and for his own part he did not see any great difficulty in agreeing with the theory of indirect bacterial causation. Professor Atkinson's interesting talk on hypo-sensitization with histamine seemed to fit in very well with other theories of allergic reactions.

He had recently been interested in seeing an elderly lady who first came to him in 1938 complaining of sudden and almost complete deafness in her right ear. She had no vertigo or signs of hæmorrhage and her labyrinth was well functioning. Various investigations were carried out. He got some insight into the condition on reading a paper showing that the changes of Ménière's disease might start in the cochlea. The cochlea might be regarded as a "shock" organ, just as allergists spoke of other organs of the body as shock organs. He gave this lady ammonium chloride to fix salt, and she now wrote to say that she was much better—the tinnitus had diminished until it was tolerable, and so far as the deafness was concerned she was now able to hear the wireless.

He had been interested in seeing a Report on the use of benadryl from the Mayo Clinic. He wondered whether this was likely to be of use in cases of primary aural vertigo.

Ménière's Disease—A Critical Review

By A. J. WRIGHT, F.R.C.S.

SOME nine years ago I first contributed a paper on this subject to this Section (*Proc. R. Soc. Med.*, 1937, 31, 87). Since that time two outstanding advances in our knowledge of Ménière's disease have been achieved in that both the clinical and pathological pictures have been defined and we now regard Ménière's disease as an entity. The fundamental cause of the disease is as yet unproven.

Clinical picture.—(1) Ménière's disease occurs in individuals at all ages and is not obviously associated with any other gross constitutional disturbance.

(2) Two types which perhaps are distinct can be recognized. The more usual one in which the lesion is essentially unilateral, and the less common one in which it is bilateral and approximately equal from the beginning. The latter cases tend to be more rapid in development and more resistant to treatment and remain for further investigation.

(3) The first signs of the disease are usually associated with the cochlea and it may possibly be of significance that this contains the vascular area which is probably in the main responsible for the secretion of endolymph.

(4) As a corollary to this many cases of perceptive deafness are explainable as being the initial stages of the disease and these are I believe usually recognizable.

(5) The most striking characteristic of the disease is its tendency to progress and to remit, such periods of remission not infrequently being of very long duration. This characteristic must be taken into account in any explanation as to the fundamental cause of the complaint.

(6) The occurrence of the vertigo in attacks is difficult of explanation. Possible explanations would seem to be: (a) A sudden obstruction to some portion of the membranous labyrinth giving rise to increase in tension, as we see in glaucoma. (b) The summation of stimuli leading eventually to an explosive response as we see in epilepsy and migraine. A combination of the above two factors is possible.

Pathological picture.—It is now established that the cause of the symptoms is to be found in a lesion in the labyrinth. The researches of Hallpike amply confirmed by others have shown, as a constant picture, a distension of the membranous labyrinth and perhaps some alteration in the constituents of the endolymph. Examination of the eighth nerve has not revealed any abnormality. That the symptoms are due to a lesion in the end-organ is also shown by the fact that its destruction or the severance of its nervous connexion with the brain will arrest the vertiginous attacks.

Theories as to the nature of the complaint.—The following considerable list has been put forward by different observers: (i) Eustachian obstruction with resulting secondary pressure changes in the labyrinth. (ii) Vascular dysfunction in the direction of spasm, dilatation, or alteration in the permeability of the capillary wall. (iii) Retention of water or electrolytes. (iv) Allergy. (v) A bacterial toxæmia.

A critical review of the above theories

Eustachian obstruction with resulting secondary pressure changes in the labyrinth: In my experience this is only found as a factor in causation when the labyrinth is itself pathological. This does not exclude the possibility of a vestibular disturbance as a result of abnormal pressure changes in the middle ear but such cases of eustachian block should not properly be included under the term Ménière's disease unless they present other evidence of a lesion in the labyrinth.

Vascular dysfunction: This may quite possibly take part in the mechanism of the complaint but does not offer any explanation as to the fundamental causation.

Retention of water or electrolytes: A similar statement can be applied to this theory. That there is a local retention of fluid in the membranous labyrinth is now proven, but I have never been able to satisfy myself that this is part of a constitutional dysfunction. That treatment directed to this factor should alleviate the symptoms is not surprising.

Allergy: By this I presume is meant a tissue reaction abnormal in degree or kind or both, to some circulating foreign substance whether bacterial or otherwise. We would expect that such increased sensitiveness might not uncommonly be present but I have been surprised to find how relatively infrequently general allergy is present in the victims of this complaint.

A bacterial toxæmia: This theory, whether correct or not, is the only one which suggests a fundamental cause for the complaint and is the one which I accept. My reasons for doing so are in the main that by its nature it would fit as a cause for a progressive but frequently remittent lesion and that, in my experience, elimination of such a factor tends to produce a remission. Most important of all, the probability of the production of such a remission seems to vary in direct relationship to the degree to which one can expect completely to eliminate the source of infection surgically; thus, for example, the most brilliant results are obtained by the extraction of a single dead or infected tooth in a young person in whom other sources of infection can be reasonably excluded.

Atkinson has recently described me as a lone figure in my support of the infective hypothesis.

I believe that I am the only worker in this field who has tried over a long period, and I hope, with some degree of scientific accuracy, to assess the truth of the infective causation.

Up to the present, as far as I am aware, only somewhat vague general statements have been made by others combating the infective hypothesis. I shall therefore continue in my belief until presented with the results of a similar investigation producing contrary findings.

Mr. E. D. D. Davis said that there was considerable evidence in favour of that theory such as the sudden explosive onset, fainting attacks and other vascular disturbances, and the increased intra-labyrinthine pressure which might explain the dilatation of the

canal of the cochlea, discovered by Hallpike. It was significant that vasodilators could produce an attack of Ménière's syndrome.

The President had mentioned eustachian obstruction. He himself had not found that eustachian obstruction had produced a true Ménière's syndrome. All the cases of true Ménière's syndrome which he had seen had a remarkably patent eustachian tube as shown by the eustachian catheter.

He thought that sepsis may be a contributory cause and there were cases which improved after the drainage of a suppurating antrum or nasal sinus. On the other hand, the extraction of teeth, enucleation of tonsils and the removal of other septic foci had no appreciable beneficial effect on the vertigo in all cases.

Mr. C. P. Wilson, who said that he had been interested in this subject for a long time, desired to ask Professor Miles Atkinson whether there was not, in addition to the positive and negative groups, a third histamine group, in which the findings were equivocal. The sensitive people were of the type who some years ago were classified as of the vagotonic type. They might properly be called potential allergics. There was a large group of normals who were not in one group or the other: their reactions were equivocal. The other interesting point about these cases was that the majority of the histamine-sensitive people had a very low blood-pressure, and they had a distinct family history of longevity. If one inquired into the family history it was rare not to find a relative who had lived to something like 85.

Mr. C. Hamblen-Thomas asked whether he was to understand that eustachian obstruction was not a factor in vertigo. He had always considered it to be a large factor.

Mr. H. V. Forster said he had rarely been able to discover a focus of sepsis responsible for vestibular vertigo in Ménière's syndrome, though he would look upon a devitalized tooth with suspicion.

In the earlier years of this century it had been the custom to indict the large bowel as a source of toxic absorption and a menace to man's longevity.

When, however, one thought of the elaborate chemical processes attending digestion in the small intestine, it might be left to the imagination to consider the consequences when these were disturbed.

He did not think that in civilian practice impaired ventilation of the eustachian tube often accounted for our cases of vestibular vertigo.

Mr. Stirk Adams considered a central disturbance in the mid-brain nuclei could produce all the symptoms of a unilateral labyrinthine vertigo, and quoted two cases in support of this thesis.

The first occurred to a doctor, twenty-five years ago, who developed a devastating attack of vertigo which persisted for six weeks. For the whole period of the attack a spontaneous nystagmus prevented fixation of external objects, but after the attack subsided, all symptoms disappeared and no deafness has ever appeared in either ear. There has been no recurrence.

He had heard of a second case, in which recurrent unilateral labyrinthine attacks had ultimately been treated by surgical destruction of the labyrinth, but this failed to give relief. The attacks disappeared, however, when the patient gave up smoking.

Dr. Miles Atkinson, in reply, confessed that he was not so sceptical of the idea of sepsis being a factor as he had formerly been; nevertheless, he was not ready to accept that as the whole explanation. He regarded Ménière's syndrome as consisting of the triad of symptoms, vertigo, tinnitus, and deafness, all three together. He was not prepared as yet to accept anything short of that. Mr. Davis had said that he always found an open eustachian tube, and he (the speaker) agreed, though undoubtedly a sudden block could produce acute vertigo temporarily. As for the incidence of associated migraine, he had seen a number of such cases. In fact, in his view one of the commonest associated symptoms of Ménière's syndrome was headache, and this was sometimes of true migraine type. Sometimes the Ménière attacks replaced the migraine attacks, so that with the first attack of vertigo the headaches ceased. He had had patients who had suffered with migraine for many years who had said: "When my dizziness started my headaches ceased." Here was another piece of evidence which tended to support the vascular thesis.

Mr. Wright had said that the vascular thesis, however good or bad, did not explain what was at the back of it all, and Mr. Wilson had forestalled him by suggesting three groups instead of two. He agreed with both speakers. He could do no more here than suggest that the basic fault is a metabolic one, admittedly a very broad term. For instance he had been doing some investigation into metabolic processes in this condition and he could say that a high blood cholesterol content had been found in many cases, whatever that may signify. In his view—he was coming to it gradually, and he thought there was a good deal of evidence for it—there was a profound metabolic disturbance which prevented the adequate utilization of vitamins and/or other nutritional factors. This metabolic disturbance could be induced by several different factors, one of which undoubtedly might well be the chronic infective focus upon which Mr. Wright was so insistent.

Mr. A. J. Wright said that he fully appreciated that there was no quarrel as between Mr. Atkinson's position and his own. Each of them might have got hold of different aspects of the same truth. He had already drawn attention to the fact that in these cases one did occasionally get a sudden onset of deafness which was difficult to explain. The occurrence of this condition in one ear and at a later date in the other was not, unfortunately, rare. There were points worth considering in this connexion, such as the extremely minute size of the membranous labyrinth. Again, there was evidence in Hallpike's work of an alteration in the endolymph, so that what was a clear fluid-like aqueous

(5) The most striking characteristic of the disease is its tendency to progress and to remit, such periods of remission not infrequently being of very long duration. This characteristic must be taken into account in any explanation as to the fundamental cause of the complaint.

(6) The occurrence of the vertigo in attacks is difficult of explanation. Possible explanations would seem to be: (a) A sudden obstruction to some portion of the membranous labyrinth giving rise to increase in tension, as we see in glaucoma. (b) The summation of stimuli leading eventually to an explosive response as we see in epilepsy and migraine. A combination of the above two factors is possible.

Pathological picture.—It is now established that the cause of the symptoms is to be found in a lesion in the labyrinth. The researches of Hallpike amply confirmed by others have shown, as a constant picture, a distension of the membranous labyrinth and perhaps some alteration in the constituents of the endolymph. Examination of the eighth nerve has not revealed any abnormality. That the symptoms are due to a lesion in the end-organ is also shown by the fact that its destruction or the severance of its nervous connexion with the brain will arrest the vertiginous attacks.

Theories as to the nature of the complaint.—The following considerable list has been put forward by different observers: (i) Eustachian obstruction with resulting secondary pressure changes in the labyrinth. (ii) Vascular dysfunction in the direction of spasm, dilatation, or alteration in the permeability of the capillary wall. (iii) Retention of water or electrolytes. (iv) Allergy. (v) A bacterial toxæmia.

A critical review of the above theories

Eustachian obstruction with resulting secondary pressure changes in the labyrinth: In my experience this is only found as a factor in causation when the labyrinth is itself pathological. This does not exclude the possibility of a vestibular disturbance as a result of abnormal pressure changes in the middle ear but such cases of eustachian block should not properly be included under the term Ménière's disease unless they present other evidence of a lesion in the labyrinth.

Vascular dysfunction: This may quite possibly take part in the mechanism of the complaint but does not offer any explanation as to the fundamental causation.

Retention of water or electrolytes: A similar statement can be applied to this theory. That there is a local retention of fluid in the membranous labyrinth is now proven, but I have never been able to satisfy myself that this is part of a constitutional dysfunction. That treatment directed to this factor should alleviate the symptoms is not surprising.

Allergy: By this I presume is meant a tissue reaction abnormal in degree or kind or both, to some circulating foreign substance whether bacterial or otherwise. We would expect that such increased sensitiveness might not uncommonly be present but I have been surprised to find how relatively infrequently general allergy is present in the victims of this complaint.

A bacterial toxæmia: This theory, whether correct or not, is the only one which suggests a fundamental cause for the complaint and is the one which I accept. My reasons for doing so are in the main that by its nature it would fit as a cause for a progressive but frequently remittent lesion and that, in my experience, elimination of such a factor tends to produce a remission. Most important of all, the probability of the production of such a remission seems to vary in direct relationship to the degree to which one can expect completely to eliminate the source of infection surgically; thus, for example, the most brilliant results are obtained by the extraction of a single dead or infected tooth in a young person in whom other sources of infection can be reasonably excluded.

Atkinson has recently described me as a lone figure in my support of the infective hypothesis.

I believe that I am the only worker in this field who has tried over a long period, and I hope, with some degree of scientific accuracy, to assess the truth of the infective causation.

Up to the present, as far as I am aware, only somewhat vague general statements have been made by others combating the infective hypothesis. I shall therefore continue in my belief until presented with the results of a similar investigation producing contrary findings.

Mr. E. D. D. Davis said that there was considerable evidence in favour of that theory such as the sudden explosive onset, fainting attacks and other vascular disturbances, and the increased intra-labyrinthine pressure which might explain the dilatation of the

The cases in Group A are all cases which have been treated during the last few months. Previously it was not felt justifiable to use penicillin in such cases, and in any event, in previous cases, incision of the tympanic membrane was done as a routine if perforation had not already occurred: these were cases in which there was temperature, pain and redness of the drum but no marked bulging, and were the type of case in which one might have incised the drum had one seen the patient at his own home or some distance away while, if in hospital, one would perhaps have said "do a paracentesis tomorrow if the condition deteriorates"—in other words, they were the cases which one would not consider to be a simple acute catarrh but cases of early suppurative otitis media. Cases which showed definite bulging were always incised and come into Group B. Group C were cases which presented definite clinical or radiological signs of mastoiditis.

All cases were treated with intramuscular injections, 23 cases during the earlier period were given 20,000 units four-hourly while 87 have been treated by doses of 60,000 three-hourly. The smallest total dose given was 600,000 units while in one or two cases nearly 7 million units have been given. 7 cases treated with the smaller doses required a second course and also one case treated with the larger dosage.

It has not been easy to dissect the statistics to be obtained from these cases as one could divide them up into multitudinous groups, in fact into nearly 110 groups, as practically no two cases were exactly alike but I have endeavoured to obtain the maximum amount of useful information that was possible.

The numbers are so small that they must in many respects be misleading and I give the actual figures without suggesting that too much reliance is placed on any percentage shown.

All the cases could be considered as acute cases although in 15 there was a possibility of the condition being labelled as acute on chronic as there was a previous history of suppuration and swabs taken from the discharge showed secondary organisms—while in 5 other cases secondary organisms were present although there had been no history of previous trouble with the ears.

Six of the cases treated were those of acute infection following traumatic perforation of the drum and these accounted for 4 of the cases which grew secondary organisms. In 25 of the cases sulphonamides were also given as part of the treatment while in 85 cases no sulphonamides were used. Of these 25, 10 were in Group B out of 50; 15 were in Group C out of 42.

The second table shows the type of infection present.

TABLE II.

Group	No.	Nil	Strep.	Staph.	Pneumo.	Others	Secondary organisms present
Group A	18	18					
Group B	50	2	26	10	6	6	16
Group C	42	1	20	9	12	—	4
		21	46	19	18	6	20

The case in Group C in which no organisms were found was an acute influenzal ear which showed intense congestion of drum and marked mastoid tenderness with dullness of the mastoid on X-ray. This was treated by penicillin only without myringotomy and cleared up completely without perforation of the tympanic membrane. It is included in Group C and not in Group A.

Cultures were taken daily while discharge was present and subsequently every other day until the tympanic membrane had healed. Discharge was seldom present after the fourth day and in most cases it was not possible to grow organisms after the second day, and in many cases indeed not after the first day.

These figures conform roughly to those generally found and would vary within wide limits in any series of cases of this size, particularly if they included cases associated with any epidemic infection.

Dosage.—Much of the work, especially in the early stages, was experimental but the cases taken as a whole seem to show quite definite tendencies. The average doses given for the various groups and organisms are as shown in Table III.

TABLE III.

	Nil	Strep.	Staph.	Pneumo.	Secondary organisms
Group A	2,500				
Group B		2,000—	2,000+	2,800	3,100
Group C		2,000—	2,500+	2,650	5,850
		"000" omitted.			

material assumed different consistency. Given those two things, it was a perfectly simple mechanical proposition that there should be from time to time a sudden obstruction of the cochlea; in fact the connexion between the cochlear and the vestibular apparatus was on the most minute scale and that, in some cases, the one should become cut off from the other was, to his mind, rather to be expected than the reverse.

Mr. Davis and he saw the world through different spectacles. Mr. Davis, he thought, had made the sweeping statement that in the vast majority of cases of Ménière's disease no focus of infection could be found. He could not agree with broad statements of that sort. Mr. Wilson had mentioned low blood-pressure. Years ago vertigo was put down to high blood-pressure until people actually began to take the pressures and came to a different view. Mr. Forster had pointed out that the intestinal tract could lead to many ills in this connexion; also that under extremely abnormal conditions of pressure a vestibular disturbance could be produced, particularly if the middle-ear adjusting mechanism was not as it should be.

Mr. Stirr Adams had suggested that some cases were not labyrinthine. He thought that what he meant was that some cases of vertigo were not Ménière's disease. He wondered what evidence there was that the actual attack was not initiated in the labyrinth. In the picture of this disease one first got an alteration of one labyrinth. It was "sensitized" for a variety of reasons. The "sensitized" labyrinth might be damaged by something which would not have caused upset to a normal one. Occasionally it was an injury. He had known on two or three occasions the thermal factor to come in, such as with undue exposure of one side of the head—a long drive in winter with the window of the car open on that side. Given that change, one presumed a circulating factor which produced this reaction. Most frequently the circulating factor was a bacterial toxin, though that was not so in all cases.

Report on 110 Cases of Acute Infection of the Ear Treated With Penicillin

By C. P. WILSON, C.V.O., F.R.C.S.

I was in the fortunate position of being attached to one of those centres to which supplies of penicillin were allocated by the Medical Research Council at a very early stage in its use.

At first the supplies were very scanty and precious and we were able to use it only in certain specific types of case—particularly those cases which were resistant to sulphonamide therapy—and from an aural point of view we were limited to serious complications of mastoid disease such as meningitis. It was not until the supplies of penicillin became somewhat easier that we were justified in using it for purposes of research, in treatment of less serious cases such as uncomplicated mastoiditis and, later still, in simple acute suppurative otitis media. This limitation of use has restricted the number of cases which have so far been available to me and has also tended to vitiate any statistics which would include all cases, as during the first year these statistics would include only those cases associated with serious complications.

I have therefore not included 12 cases of acute infection of the ear with such complications as meningitis and apical petrositis although I have details of these cases with me and can refer to them if the subsequent discussion demands it.

In this present paper I am referring to a total of 110 cases treated with penicillin and before going any further would like to thank those of my colleagues who have allowed me to use the cases which have been under their care, particularly my colleague at the Middlesex Hospital, Mr. Monkhouse.

For convenience I have divided these cases into three groups:

- A. Consists of 18 cases of acute uncomplicated otitis media without perforation.
- B. Comprised 50 cases of acute suppurative otitis media in which spontaneous perforation occurred or in which the drum was incised, that is, discharging ears without definite signs of mastoiditis.
- C. Comprised 42 cases associated with a definite mastoiditis.

TABLE I.

	No. of cases	Secondary organisms present	Sulphonamides	Traumatic perforations
Group A	18	—	—	—
Group B	50	16	10	4
Group C	42	4	15	2
	110	20	25	6

Of those with secondary organisms { History of previous suppuration 15.
No history of previous suppuration 5.
Myringotomy was performed in 17 cases: 14 in Group B and 3 in Group C.
A mastoid operation was performed in 12 cases in Group C.

be greater than is necessary but in no cases of this group was a second course of treatment necessary. The one case of impaired hearing is in a child who had some degree of nasal obstruction and subsequent treatment of this condition has not, so far, improved the hearing.

Pain and temperature subsided very quickly, often within twelve hours but it is doubtful if this advantage compensates completely for having to have treatment for six days.

The dosage rather surprisingly has been greater than the average required for either streptococcal or staphylococcal infections in both Groups B and C and one cannot help feeling that the drainage provided by the perforation of the tympanic membrane is the main factor in reducing the dosage required. I think it would be reasonable to treat a group of similar cases with early myringotomy and compare the doses required.

I cannot help feeling that the main factor in the treatment of early acute infections of the ear still remains adequate drainage and if this does not occur naturally via the eustachian tube at a very early stage, incision of the drum is not favourably replaced by chemotherapy, either sulphonamide or penicillin.

In the other groups it is interesting to note that the pneumococcal infections needed considerably larger doses of penicillin than the others and those cases with secondary infections took, in some cases, huge doses and even so the results compare very unfavourably with simple strep. and staph. infections.

The great danger, to my mind, now that penicillin has become universally available is that it will be used by the general practitioner with the main object of providing the advantage of relief of acute symptoms and that once this object has been achieved there will be passive and even active resistance on the part of the patient or relatives to the continuation of treatment. This will, I fear, result in relapse with recurrence of the infection needing a subsequent course of treatment and worse still will turn the acute infection into a chronic or exudative otitis media with continued and permanent impairment of hearing.

It is this subsequent impairment of hearing which to my mind is the most serious danger which we will have to face and I cannot too strongly urge that even if all other symptoms have cleared up a case cannot be considered completed until the hearing has been restored to the best possible level.

We have had to face this problem during the last nine or ten years with the sulphonamides, and although it may be that penicillin presents considerable advantage in its efficiency, the very fact of its application being more unpleasant than the taking of tablets by mouth may produce for us the same problem but on a larger scale.

To sum up, penicillin is not *the* treatment of acute otitis media, it is an ancillary method. Treatment remains efficient drainage, and to the extent that by the use of penicillin these functions are reversed so great will be its menace.

The President said that he was pleased to note, on the one hand, the emphasis Mr. Wilson laid upon the question of hearing—which he was afraid they did tend rather to neglect—and, on the other, his warning against regarding a treatment because it was new as necessarily a substitute for anything one did in the past.

Mr. R. R. Simpson said that they had listened to some very impressive figures that morning, and he wanted to congratulate Mr. Wilson on his accurate and critical analysis of these cases. In the Services he himself had not been so impressed with the efficacy of penicillin in acute otitis media but he realized the important difference in his figures from those brought forward by Mr. Wilson. In dosage he had used 20,000 units instead of Mr. Wilson's 60,000, and since listening to him he wondered whether in the secondary infection type of case where massive doses had to be given they could not consider proceeding along the same lines of massive dosage as in gonorrhoea, e.g. 300,000. Mr. Wilson's figures certainly made him feel like trying again with a more adequate dosage. The massive dose would certainly get over the question of dose frequency, and he knew of no objection to it.

The essential surgical principle should be preserved—where there was pus it should be let out. The maintenance of the patency of the eustachian tube was important, and here he desired to mention the experience he had had during six years of war in the Services. He had found the use of ephedrine-saline, either as spray or drops—preferably drops—in the head-hanging position, combined with the administration of alkalis by mouth, as helping to re-establish the patency of the eustachian tube in a great many cases. He knew there were objections to the alkali method, but in actual working out it did prove effective.

The other point concerned the return to normal hearing. In the treatment of these cases by inadequate doses of sulphonamides, granulations formed in the middle ear. This had been found in other fields, e.g. in quinsies, where sulphonamide dosage had been inadequate, granulation tissue formation was excessive. While the acute symptoms in

It seems quite clear that the hæmolytic streptococci respond most quickly and the pneumococci least quickly while cases with secondary infections are very resistant. This again would conform to our previous impressions.

The most interesting fact which emerges from these figures is that the average dose required in Group A, 2,500,000 units, is larger than that used in all cases of strep. and staph. infections in both Groups B and C.

Results of treatment.—The two main criteria are (1) restoration of hearing, and (2) a dry ear. There are fortunately no deaths to record in this series. The mortality of this disease, particularly with regard to its serious complications, has undergone a marked change since the advent of the sulphonamides and penicillin.

From the point of view of the restoration of hearing it is difficult to assess the results as one feels that a not inconsiderable number of those cases in which the hearing remained impaired after treatment already had some hearing loss before the attack for which they were treated.

The actual results are as shown in Table IV.

TABLE IV.					
	No. of cases	Very poor	Impaired	No complaint or normal	Percentage with loss of hearing
Group A	18	—	1	17	6
Group B	50	2	7	41	18
Group C	42	2	14	26	38
Total	110	4	22	84	24
Simple infection	90	2	14	74	17.8
Sec. organisms present	20	2	8	10	50
20,000 units	23	2	6	15	35
60,000 units	87	2	14	71	18

It is fair to assume that the majority of these cases showing secondary organisms had some impairment of hearing before treatment and if these cases were removed from the list there remains hearing loss in 16 cases out of 90 or 17.8%. Out of the 23 treated with the smaller doses 8 had some impairment of hearing, 35%, while with the larger doses the % is 18.

Table V shows continuance of discharge.

TABLE V.—DISCHARGE.					Percentage with discharge
		Discharge	Dry		
All cases	110	8	102		7
Simple infections	90	1	89		1
Sec. organisms	20	7	13		35
20,000	23	5	18		22
60,000	87	3	84		3

This continued in 8 cases while in 102 a dry ear resulted, that is roughly 7%. Seven of these cases were those with secondary organisms present while the other case was originally a staphylococcus four times resistant. Two of the cases with moist ears were associated with traumatic perforations, one of which had previously been treated with drops and the other occurred while swimming. Five of the cases had the smaller dose while three had 60,000 units. These are the bare figures and the most difficult part of my task is to decide what conclusions can reasonably be drawn from them.

In the first place one cannot but help noticing the difference in the results of treatment by doses of 20,000 units per injection as compared with higher doses.

For hearing results the comparative figures of hearing loss are 35% as compared with 18%, while for persistent discharge they are 22% as compared with 3%. These results are ample confirmation of the wisdom of using the increased dosage.

I regret that I cannot give any useful statistics of the comparative results of those cases treated with and without sulphonamides. Unfortunately, many of them were treated—often with inadequate doses—before coming under our care so that comparison would be misleading.

This is a pity because there have been reports recently of acute infections treated by a combination of penicillin and sulphonamides in which the results of the combined treatment are of a very satisfactory nature.

In the next place I think some significance attaches to the figures of dosage in Group A. Obviously no hard and fast rules can be laid down in any particular case and our practice has been to carry on with treatment until the congestion of the drum has subsided and the landmarks are again clearly established. This has meant that treatment has gone on for five or six days as an average in this group. This dosage may perhaps

COMBINED SUMMER MEETING HELD IN TORQUAY

[June 14, 1946]

LARYNGOLOGICAL SESSION

Chairman—G. EWART MARTIN, F.R.C.S.Ed.

(President of the Section of Laryngology)

The Application of Electromyography to Affections of the Facial and the Intrinsic Laryngeal Muscles

By B. FEINSTEIN.

ELECTROMYOGRAPHY is a delicate gauge of the damage to the lower motor neuron and it has proved of value for the accurate assessment of peripheral nerve injuries and the early stages of diseases affecting the lower motor neuron. Among other pathological conditions, it has been an aid in the diagnosis and prognosis of facial and laryngeal muscle affections (Weddell, Feinstein and Pattle, 1944). Muscles which perform finely graded movements such as those of the face and larynx have motor units composed of fewer muscle fibres than those muscles, such as of the limb, which are only capable of much coarser movements. The action potentials are similarly less in duration (2 to 5 milliseconds) and smaller in amplitude (50 to 500 microvolts).

Facial paralysis.—Electromyographic examinations have been carried out in more than 150 cases of facial paralysis due to affection of the lower motor neuron. The cause of the paralysis, in the majority of the cases, can be divided into two clearly defined groups.

In the first group, the paralysis is due to trauma, either direct or indirect, and in the second, the paralysis is due to pressure by inflammatory oedema on the nerve trunk in its course through the temporal bone, resulting in an ischaemic block. In this group can be included the paralysis found in such conditions as Bell's palsy, herpes zoster and otitis media.

It has been found that the facial paralysis following a head injury in the majority of cases is apparently due to an ischaemic block rather than to an interruption of the axons. This would account for the observations of Turner (1944) that the prognosis in facial paralysis of this type is good. 12 cases of traumatic facial paralysis were examined electromyographically. In 4 of these, there was no evidence of denervation and each made a complete recovery, but, in each of the other cases, there was a varying number of axons interrupted. Recovery occurred but associated movements were present in every instance.

The findings suggest that in cases of complete axonal interruption following direct trauma, where there is no gross displacement of the nerve, at least six months should elapse before operative procedures, such as exploration and grafting, are to be considered. In such cases electromyographic examinations are valuable in detecting minimal degrees of re-innervation before the return of functional recovery. In those cases where the skiagrams demonstrate a fracture and displacement of the mastoid tip, earlier operation is justified. In cases of closed head injuries, the prognosis regarding the recovery of facial paralysis is so good that early decompression of the facial nerve is not warranted.

the ear subsided, deafness remained, due to the contraction of the granulation tissue. He wondered whether something similar happened in ears where the dosage of penicillin was inadequate.

Mr. G. H. Bateman said that Group A bothered him very considerably. It was almost impossible to estimate whether to leave the condition alone or not in these cases, and any figures produced for Group A seemed to him rather in the realm of guesswork. Perhaps Mr. Wilson would define a little more clearly whether he had referred to cases in which suppuration had occurred or cases in which he thought it might occur.

Mr. H. V. Forster said that he was grateful that this point had been brought forward by Mr. Wilson and Mr. Bateman. Mr. Wilson had stated that these were cases of potentially acute suppurative otitis media.

He, Mr. Forster, had always disliked the academic distinction made between acute catarrhal and acute suppurative otitis media when it was meant to imply that the former was a less severe type of the same disease.

The term, acute catarrhal, might lead to confusion in our conception of exudative catarrhal otitis media or "secretory otitis media" (see Eagle, Watt W. (1946) *Annals Otol. Rhino., Laryng.*, St. Louis, M.O., U.S.A., 55, 55).

Mr. Gavin Livingstone spoke of cases of mastoiditis in which much smaller doses than those mentioned by Mr. Wilson had been given, namely, 20,000 units of penicillin. There had been no surgical interference. Out of 16 cases there had been five failures; the others had cleared up entirely. In the cases which were failures there was no adequate drainage. In two cases the middle ear was not draining at all. The conclusion was that penicillin was of no use unless drainage was taking place through the middle ear. Future cases might be tried on larger doses.

Mr. C. P. Wilson, in reply, said that he was neither advocating nor defending penicillin. He was not suggesting that he would ever treat another group such as the A group. He started treating the A group four months ago when he was first asked if he would take part in this discussion, and it was solely to see what information he might obtain by treating these cases that he did so. They were cases which, if left, would have become cases of acute suppurative otitis media. The difficulty in those cases with definite mastoiditis lay in telling beforehand that they were of a type which would not respond completely to penicillin. Failure might be associated with the size of the individual cell; there might be so much pus in the cells that the penicillin did not get into them. It might be possible to get a clue by X-ray picture of the anatomy of the cell distribution.

He thoroughly agreed as to the importance of early puncture of the drum; all cases should have a myringotomy done at an early opportunity. The treatment for acute suppurative otitis or acute otitis media that might be suppurative was really still myringotomy. So far as dosage with penicillin was concerned, no difference was made in this series with regard to age; it was the same for the infant as for the adult. Local penicillin was not used in any of these cases.

Electromyographic examination has been found to be of value in cases of "idiopathic laryngeal palsy". In a few of these cases, normal motor unit activity was obtained from the muscles which were thought to be affected, and the immobility of the cords was shown to be due to ankylosis of the arytenoid cartilage. A certain degree of recovery in these cases is possible by re-education. Vocal cord paralysis as a result of denervation of the intrinsic laryngeal muscles was diagnosed by the presence of fibrillation action potentials. In these cases, recovery was not so good although it was possible at times to pick up polyphasic motor unit action potentials indicative of re-innervation.

R. G. Macbeth described electromyography of the laryngeal muscles, first giving the technique and then proceeding to some illustrative cases. The patient was premedicated and prepared with surface anaesthesia as for any direct laryngoscopy, and the larynx was examined by the ordinary routine. Any diagnostic laryngoscope might be employed. Usually the crico-arytenoideus lateralis muscle was initially explored, on the unaffected side first and then on the affected side. Then the posticus muscles were similarly explored. The lateralis muscle was reached by inserting the bipolar electrode through the aryepiglottic fold lateral to the cord. The posticus muscle was reached by passing the beak of the laryngoscope behind the arytenoids to each side of the mid-line in turn and inserting the electrode 1 to 2 cm. below the level towards the back of the cricoid cartilage. The patient was instructed to phonate or breathe deeply as required. By this technique doubtful cases of paralysis, crico-arytenoid fixation, and hysterical aphonia might be diagnosed with reasonable certainty. No untoward effects of the examination, except slight soreness, had been noted to date.

Mr. Macbeth then mentioned three illustrative cases:

(1) A lieutenant in the U.S. Army Air Corps was hit in the neck by a piece of flak. This had entered anteriorly on the right side and come to rest in the posterior muscles. He had become hoarse immediately after being struck, and remained so. Laryngoscopy showed the right cord immobile in the cadaveric position. Electromyography one month later revealed complete axonal interruption of the recurrent nerve on that side.

(2) A sergeant in the same Corps was hit in the neck near the larynx on the right side by flak. There was a history of considerable swelling in the region of the thyroid cartilage, which had subsided, and of hoarseness, which had persisted. Laryngoscopy two months later showed the right cord fixed in abduction and some thickening of the aryteno-epiglottic fold. Electromyography showed intact innervation on the affected side. Crico-arytenoid ankylosis, already suspected clinically, was thus confirmed.

(3) A Guardsman was undergoing preliminary training when he fell upon a tree-trunk and badly bruised the right side of his neck. There was considerable swelling, which subsided, and hoarseness, which persisted for six months. He had been discharged from the Army with a diagnosis of recurrent laryngeal nerve paralysis, after having been examined by a number of otolaryngologists. When seen in civilian life the right cord was in the cadaveric position and nothing else was to be made out clinically. X-rays of the laryngeal cartilage showed no fracture. Electromyography of the laryngeal musculature showed full motor activity on the affected side. His discharge diagnosis was thus disproved, and it became clear that he had a fixation of the crico-arytenoid joint.

A New Œsophagoscope

Martin Henry said that the distally illuminated œsophagoscope of the tubular type gave admirable illumination at the position where it was most needed, but it was difficult to manipulate, and being necessarily of the tubular pattern the field of view was restricted. The disadvantage of the proximally illuminated type of instrument was that, while giving an admirable open field at the end of the scope, it had diminished illumination.

He had designed an œsophagoscope which gave an open field of view at the distal end, was easy to manipulate, and afforded adequate illumination. A definite improvement in the illumination of proximally illuminated instruments could be obtained by aligning the lamps so that they bore directly on the distal end of the instrument. Existing instruments carrying their lights in long tubes were focused on the walls of the main tube, the illumination finally reaching the tip of the œsophagoscope by means of cross reflection, so that a proportion of the illuminating power of each bulb was lost. In his instrument the lamp-carrying tubes, instead of being some inches long, were only just long enough to prevent reflection from the bulb reaching the surgeon's eye. In this instrument the lamp-carrying tubes were inside the œsophagoscope. If the instrument was examined without the lamp-carrying saddle in it it would be noted that whether

It is not possible by means of electromyographic examination to differentiate between an axonal interruption and a reversible ischaemic block for about twelve to fourteen days following the nerve injury, as it is not until this time that fibrillation commences.

The demonstration of even a single repetitive motor unit action potential is of great prognostic significance in a case in which clinically the paralysis is complete, as it indicates that a few nerve fibres have escaped damage, and therefore suggests that the lesion is "in continuity".

In the cases of the infective group, i.e. Bell's palsy, herpes zoster and otitis media, electromyographic examinations confirm the clinical observations, but, in addition, offer a more detailed analysis of the nature of the paralysis. This is particularly valuable in assessing the prognosis. In mild cases of facial paresis, there was a reduction of motor unit activity in response to a maximum voluntary effort to move the muscles but no other abnormalities. Recovery both clinically and as shown by means of electromyographic recordings was complete within a few weeks. In instances where the facial weakness was more marked and associated with a considerable degree of lower motor neuron denervation, recovery resulted in marked associated movements. This is accounted for by the fact that many of the regenerating axons do not follow their original pathways and dichotomization of the axon is frequent. The work of Howe, Tower and Duel (1937) has placed the phenomenon of associated movement following re-innervation on an anatomical basis, and the ultimate prognosis regarding the dissociated movement of the facial muscles is poor in view of this abnormal pattern of innervation. It may be possible, however, in some instances to improve the degree of recovery. Two cases of facial paralysis, in which there was complete axonal interruption, were followed through to functional recovery and their treatment carefully controlled. They were started on a daily session of "galvanism" and were also shown how to massage their faces, which they did a number of times daily. In addition, the angle of the mouth was kept elevated by means of a "facial" hook. Electromyographic recordings were made at weekly intervals and soon after the appearance of the first motor unit action potentials slight movement was observed on attempted voluntary contraction. The "galvanism" was then stopped and the patient began to practise individual facial movements in front of a mirror every day. The mode of regeneration and basis of associated movements were explained to the patients. In both instances, the patients were co-operative and in both cases associated movements were less than was usually seen.

Ballance and Duel (1932) have advocated that the facial nerve should be decompressed immediately a facial paralysis is seen in order to prevent axonal interruption, but, in view of the work of Denny-Brown and Brenner (1944a and b), it does not seem likely that many operations could be carried out in time to be effective. Furthermore, it is doubtful, from the anatomical point of view, whether exposure of the facial nerve from the lateral semicircular canal to the stylomastoid foramen and incising its sheath, is an adequate decompression. Kettel (1943) analysed a large number of cases of facial paralysis, associated with otitis media or mastoid infection, but came to no definite conclusion as to the optimum time for operation. He was, however, of the opinion that, in cases of immediate complete facial paralysis following mastoidectomy or labyrinthectomy, the facial nerve should be explored within seventy-two hours. In these cases, the operation of decompression seems to be of theoretical rather than practical value.

In one case of Bell's palsy, the paralysis persisted for six weeks but at no time was fibrillation, indicative of a lower motor neuron denervation, detected and recovery was complete and movements were normal. This is of interest for it suggests that the condition of a reversible ischaemic block may persist for very long periods.

There were three cases of very long-standing paralysis in which there was marked contracture. The contracture was confirmed as being due to fibrous metaplasia, for there were numerous areas of electrical "silence" in the facial muscles when electromyographic examinations were made. These patients had received no physiotherapy.

The intrinsic laryngeal musculature.—In order to record the action potentials from the intrinsic muscles of the larynx, it was necessary to use a concentric needle electrode of sufficient length so that all manipulations could be carried out through a laryngoscope.

The intrinsic muscles of the larynx have been investigated in a number of cases. The motor unit action potentials resemble those obtained from the facial musculature. The needle was first inserted into the lateral crico-arytenoid muscles and the subject requested to abduct the cords by taking a deep breath. There was continuous motor activity as long as the cords were abducted. When the cords were adducted, the motor unit activity decreased but did not die away completely. Thus the abductor muscles, even when the cords are adducted, maintain a certain amount of "tone".

Electromyographic examination has been found to be of value in cases of "idiopathic laryngeal palsy". In a few of these cases, normal motor unit activity was obtained from the muscles which were thought to be affected, and the immobility of the cords was shown to be due to ankylosis of the arytenoid cartilage. A certain degree of recovery in these cases is possible by re-education. Vocal cord paralysis as a result of denervation of the intrinsic laryngeal muscles was diagnosed by the presence of fibrillation action potentials. In these cases, recovery was not so good although it was possible at times to pick up polyphasic motor unit action potentials indicative of re-innervation.

The patient was instructed to phonate or breathe deeply as required. By this technique doubtful cases of paralysis, crico-arytenoid fixation, and hysterical aphonia might be diagnosed with reasonable certainty. No untoward effects of the examination, except slight soreness, had been noted to date.

Mr. Macbeth then mentioned three illustrative cases:

(1) A lieutenant in the U.S. Army Air Corps was hit in the neck by a piece of flak. This had entered anteriorly on the right side and come to rest in the posterior muscles. He had become hoarse immediately after being struck, and remained so. Laryngoscopy showed the right cord immobile in the cadaveric position. Electromyography one month later revealed complete axonal interruption of the recurrent nerve on that side.

(2) A sergeant in the same Corps was hit in the neck near the larynx on the right side by flak. There was a history of considerable swelling in the region of the thyroid cartilage, which had subsided, and of hoarseness, which had persisted. Laryngoscopy two months later showed the right cord fixed in abduction and some thickening of the aryteno-epiglottic fold. Electromyography showed intact innervation on the affected side. Crico-arytenoid ankylosis, already suspected clinically, was thus confirmed.

(3) A Guardsman was undergoing preliminary training when he fell upon a tree-trunk and badly bruised the right side of his neck. There was considerable swelling, which subsided, and hoarseness, which persisted for six months. He had been discharged from the Army with a diagnosis of recurrent laryngeal nerve paralysis, after having been examined by a number of otolaryngologists. When seen in civilian life the right cord was in the cadaveric position and nothing else was to be made out clinically. X-rays of the laryngeal cartilage showed no fracture. Electromyography of the laryngeal musculature showed full motor activity on the affected side. His discharge diagnosis was thus disproved, and it became clear that he had a fixation of the crico-arytenoid joint.

A New Œsophagoscope

Martin Henry said that the distally illuminated œsophagoscope of the tubular type gave admirable illumination at the position where it was most needed, but it was difficult to manipulate, and being necessarily of the tubular pattern the field of view was restricted. The disadvantage of the proximally illuminated type of instrument was that, while giving an admirable open field at the end of the scope, it had diminished illumination.

He had designed an œsophagoscope which gave an open field of view at the distal end, was easy to manipulate, and afforded adequate illumination. A definite improvement in the illumination of proximally illuminated instruments could be obtained by aligning the lamps so that they bore directly on the distal end of the instrument. Existing instruments carrying their lights in long tubes were focused on the walls of the main tube, the illumination finally reaching the tip of the œsophagoscope by means of cross reflection, so that a proportion of the illuminating power of each bulb was lost. In his instrument the lamp-carrying tubes, instead of being some inches long, were only just long enough to prevent reflection from the bulb reaching the surgeon's eye. In this instrument the lamp-carrying tubes were inside the œsophagoscope. If the instrument was examined without the lamp-carrying saddle in it it would be noted that whether

It is not possible by means of electromyographic examination to differentiate between an axonal interruption and a reversible ischæmic block for about twelve to fourteen days following the nerve injury, as it is not until this time that fibrillation commences.

The demonstration of even a single repetitive motor unit action potential is of great prognostic significance in a case in which clinically the paralysis is complete, as it indicates that a few nerve fibres have escaped damage, and therefore suggests that the lesion is "in continuity".

In the cases of the infective group, i.e. Bell's palsy, herpes zoster and otitis media, electromyographic examinations confirm the clinical observations, but, in addition, offer a more detailed analysis of the nature of the paralysis. This is particularly valuable in assessing the prognosis. In mild cases of facial paresis, there was a reduction of motor unit activity in response to a maximum voluntary effort to move the muscles but no other abnormalities. Recovery both clinically and as shown by means of electromyographic recordings was complete within a few weeks. In instances where the facial weakness was more marked and associated with a considerable degree of lower motor neuron denervation, recovery resulted in marked associated movements. This is accounted for by the fact that many of the regenerating axons do not follow their original pathways and dichotomization of the axon is frequent. The work of Howe, Tower and Duel (1937) has placed the phenomenon of associated movement following re-innervation on an anatomical basis, and the ultimate prognosis regarding the dissociated movement of the facial muscles is poor in view of this abnormal pattern of innervation. It may be possible, however, in some instances to improve the degree of recovery. Two cases of facial paralysis, in which there was complete axonal interruption, were followed through to functional recovery and their treatment carefully controlled. They were started on a daily session of "galvanism" and were also shown how to massage their faces, which they did a number of times daily. In addition, the angle of the mouth was kept elevated by means of a "facial" hook. Electromyographic recordings were made at weekly intervals and soon after the appearance of the first motor unit action potentials slight movement was observed on attempted voluntary contraction. The "galvanism" was then stopped and the patient began to practise individual facial movements in front of a mirror every day. The mode of regeneration and basis of associated movements were explained to the patients. In both instances, the patients were co-operative and in both cases associated movements were less than was usually seen.

Ballance and Duel (1932) have advocated that the facial nerve should be decompressed immediately a facial paralysis is seen in order to prevent axonal interruption, but, in view of the work of Denny-Brown and Brenner (1944*a* and *b*), it does not seem likely that many operations could be carried out in time to be effective. Furthermore, it is doubtful, from the anatomical point of view, whether exposure of the facial nerve from the lateral semicircular canal to the stylomastoid foramen and incising its sheath, is an adequate decompression. Kettel (1943) analysed a large number of cases of facial paralysis, associated with otitis media or mastoid infection, but came to no definite conclusion as to the optimum time for operation. He was, however, of the opinion that, in cases of immediate complete facial paralysis following mastoidectomy or labyrinthectomy, the facial nerve should be explored within seventy-two hours. In these cases, the operation of decompression seems to be of theoretical rather than practical value.

In one case of Bell's palsy, the paralysis persisted for six weeks but at no time was fibrillation, indicative of a lower motor neuron denervation, detected and recovery was complete and movements were normal. This is of interest for it suggests that the condition of a reversible ischæmic block may persist for very long periods.

There were three cases of very long-standing paralysis in which there was marked contracture. The contracture was confirmed as being due to fibrous metaplasia, for there were numerous areas of electrical "silence" in the facial muscles when electromyographic examinations were made. These patients had received no physiotherapy.

The intrinsic laryngeal musculature.—In order to record the action potentials from the intrinsic muscles of the larynx, it was necessary to use a concentric needle electrode of sufficient length so that all manipulations could be carried out through a laryngoscope.

The intrinsic muscles of the larynx have been investigated in a number of cases. The motor unit action potentials resemble those obtained from the facial musculature. The needle was first inserted into the lateral crico-arytenoid muscles and the subject requested to abduct the cords by taking a deep breath. There was continuous motor activity as long as the cords were abducted. When the cords were adducted, the motor unit activity decreased but did not die away completely. Thus the abductor muscles, even when the cords are adducted, maintain a certain amount of "tone".

E. D. D. Davis said that one of the disadvantages of the use of radium implantation was that there was considerable suppuration and a puckered scar was left in the neck. For his own part, if he could not have a complete excision and if he had to have radium or deep X-rays, he would prefer X-ray therapy.

The Chairman said that in Edinburgh they had a cancer research department of which the radiologist was in charge. In every case from the pathology department which was diagnosed as tumour, a report was sent direct to the cancer research department. If the growth was in the centre of the cord, extending slightly below, it was considered very much better to use radium, but if further back this was thought to be useless. Teleradium had been almost given up in favour of deep X-rays of heavy voltage, nearly up to one million. The fenestration operation gave a better voice result than the treatment of the cord by deep X-rays. When there was recurrence after the use of deep X-rays nothing could be done apart from attempting laryngofissure, but if radium needles had been used, deep X-rays could be used later on from the opposite side with suitable screening.

V. E. Negus said that he would not like to give the impression that he recommended abandonment of operation. For a limited growth of a low grade, clear of the vocal process of the arytenoid, laryngofissure was a suitable treatment. It was a certain operation; the voice was not quite as good as after irradiation, but there were none of the unpleasant after-effects that might be associated with any form of irradiation, and the voice was serviceable for all purposes. It would be a pity if the operation were abandoned. It was for the case where laryngectomy would ordinarily be required, that radium must be considered. He did not know whether Mr. Hogg was recommending that laryngofissure should be abandoned; many people felt that the case most suitable for irradiation was the case also most suitable for operation. If one could expect 75 or 80% of success with the laryngofissure operation, that should be a recommendation.

J. C. Hogg said that the question whether laryngofissure should be retained or abandoned was entirely one for the individual surgeon. Those accustomed to use radium could produce results equally good from the mortality point of view as those accustomed to do laryngofissure; but in the hands of the occasional user of radium the results were not so good.

Xanthoma of Upper Jaw.

Man, aged 39, ex-R.A.F. Admitted March 1946 with proptosis and failure of vision in right eye. X-rays showed opacity of right antrum. Exploration revealed a large encapsulated tumour expanding the antrum; this was removed. Severe hæmorrhage necessitated packing. There was still a fistula on discharge from hospital on May 1. Vision improved from 6/60 to 6/9, with disappearance of central scotoma and improvement of field. The fistula has now healed and the nose is normal.

W. H. Bradbeer said that this was one of those cases which looked formidable at first but ended happily. Xanthomata were not uncommon in the skull, especially in the petrous bone. Sometimes they were single, but there were multiple cases occurring especially in the long bones. In some cases there was also proptosis and disturbance of pituitary function, and the condition was known as the Hand-Schüller-Christian syndrome. One interesting point was that this condition tended to occur in jaundiced patients. This patient was suffering on admission from a sharp attack of benign tertian malaria, with a marked anaemia (Hb. 60%) so that it was possible he might have some hæmolytic jaundice in connexion with his xanthoma.

Blastomycosis of Nasal Mucosa (Shown by Dr. ALLEN at Mr. BRADBEER'S request).

Woman, aged 63. Treated since April 1945 for extensive blastomycotic lesions of skin. Great improvement following X-rays, potassium iodide and gold treatment. Nose shows small perforation of septum and granular condition of inferior turbinates from which the *Blastomyces dermatitidis* has, on one occasion, been identified.

H. W. Allen (Exeter) said that this was one of the first cases of the American type described in this country. The patient was first seen by him in April 1945, complaining of skin trouble affecting the cheeks and nose for a year. There were a number of minor complaints—chilblains, &c. Two or three years previously she had laryngitis. The present skin trouble started as a rash under the skin, later forming a crust; when the crust came off, a red patch was exposed and pus could be expressed. Microscopic examination of the pus showed typical blastomycetic mycelium and yeast-like double-contoured cells, which he thought he confirmed by culture. [He showed two cultures which had been obtained from the case shown and from another case of ulcerative blastomycosis; the latter had been reported on as a blastomycosis, but this appeared to him to be questionable: the former was considered to show a fairly typical colony of *Blastomyces dermatitidis* with abruptly rising edge and eccentric areola.] There was no question of residence abroad in this case, and the only suggestion that this could be American blastomycosis came from the fact that American negro troops had been in the

the observer looked through the lumen of the main tube or down either of the empty lamp-carrying tubes a complete view of the field afforded by the tip of the instrument was obtained.

He had had these instruments made in very much larger sizes than usual, first because the larger the instrument the easier it was to find the way into the œsophagoscope, and secondly because the chief limitation to the size of the œsophagoscope was not the size of the œsophagus, which was enormously dilatable, but the anteroposterior space between the upper and lower teeth. One of these models was built for edentulous adults and in spite of its large size would pass freely down the œsophagus of any edentulous adult without inflicting any trauma.

These œsophagoscopes were made in the following sizes: 30 cm. for children; 40 and 30 cm., medium adult; 40 and 30 cm., large adult; 40 and 30 cm., edentulous adult.

[June 15, 1946]

CLINICAL MEETING AT TORBAY HOSPITAL

Chairman—G. EWART MARTIN, F.R.C.S.Ed.

(President of the Section of Laryngology)

X-ray Films of Radium Needles *in situ* following Fenestration Operation.

The operation was performed by Mr. Negus and Mr. Bradbeer in December 1941. Dosage 8,640 mg. hrs. Patient free from recurrence, but in September 1945 had an attack of perichondritis and coughed up a piece of cartilage.

V. E. Negus said that this was an elderly man who was considered unfit for an excision operation, with a growth which extended along one cord. The moral of the case was that there was a use for the application of radium to the larynx. It seemed to him that radium was more logical than radon. Deep X-ray treatment for the larynx he thought to have disadvantages, and it was upsetting to the patient. Teleradium with a 5-gramme unit was less so, but many patients complained during the treatment and some wanted to stop it. It took four to five weeks, whereas the application of radium needles might be over in about seven days. The previous week he had seen a patient who had had the larynx irradiated by teleradium four years ago and had had a mild perichondritis ever since. This did not seem to occur so much with needles. The present patient had been perfectly well for some years, and then this attack of perichondritis developed four years after the operation. He could not think that Mr. Harmer's recommendation to use radium needles should be put aside without due thought; there seemed to be certain conditions in which it might be a very suitable form of treatment.

The Chairman said that he had had two cases in which the condition had apparently cleared up, and after eighteen months or two years perichondritis had developed on the other side.

V. E. Negus said that the dosage might have been a little higher than necessary. Harmer now recommended four vertical and two horizontal needles—a total of 10 mg. for seven days. He thought the way to avoid perichondritis developing on the opposite side was to ensure that the foremost needle was not too near to the cut edge of the thyroid ala.

J. C. Hogg said that he had assisted Mr. Douglas Harmer in a large number of these cases and could vouch that they did extremely well on the average. The actual screcnage was extremely important, if the development of perichondritis immediately or subsequently was to be avoided. Mr. Harmer had originally employed 0.5 mm. platinum filter, but he went rapidly to 0.6 and now never employed anything less than 0.8, and with this he had had far less trouble with post-operative sepsis and subsequent perichondritis. In fact, he had not had perichondritis due to this operation for some time now.

On the question of a horizontal or vertical palisade, a team of physicists at Mount Vernon produced a paper on the physics of the arrangement, showing just where the maximum dosage was received. He joined issue slightly with Mr. Negus as to the indications for this procedure. By and large, those cases which had a growth extending on to the arytenoid were not so favourable from the physical aspect. The intensity was not retained in that area owing to the depth of the growth from the needle, and therefore those cases had not relatively as good a prognosis as they would have with laryngectomy. On the other hand, it could be said quite definitely that cases which were limited to the middle third of the cord or the anterior commissure would obtain cure or relief as readily as the cases which had the cord removed, and with much better voices afterwards. There was no doubt that of the two elements, radon or radium, radium needles were far better. Mr. Harmer was unable for a short period at the beginning of the war to obtain radium needles and had to use radon for a time. In his opinion the radium needles were far better.

E. D. D. Davis said that one of the disadvantages of the use of radium implantation was that there was considerable suppuration and a puckered scar was left in the neck. For his own part, if he could not have a complete excision and if he had to have radium or deep X-rays, he would prefer X-ray therapy.

The Chairman said that in Edinburgh they had a cancer research department of which the radiologist was in charge. In every case from the pathology department which was diagnosed as tumour, a report was sent direct to the cancer research department. If the growth was in the centre of the cord, extending slightly below, it was considered very much better to use radium, but if further back this was thought to be useless. Telradium had been almost given up in favour of deep X-rays of heavy voltage, nearly up to one million. The fenestration operation gave a better voice result than the treatment of the cord by deep X-rays. When there was recurrence after the use of deep X-rays nothing could be done apart from attempting laryngofissure, but if radium needles had been used, deep X-rays could be used later on from the opposite side with suitable screening.

V. E. Negus said that he would not like to give the impression that he recommended abandonment of operation. For a limited growth of a low grade, clear of the vocal process of the arytenoid, laryngofissure was a suitable treatment. It was a certain operation; the voice was not quite as good as after irradiation, but there were none of the unpleasant after-effects that might be associated with any form of irradiation, and the voice was serviceable for all purposes. It would be a pity if the operation were abandoned. It was for the case where laryngectomy would ordinarily be required, that radium must be considered. He did not know whether Mr. Hogg was recommending that laryngofissure should be abandoned; many people felt that the case most suitable for irradiation was the case also most suitable for operation. If one could expect 75 or 80% of success with the laryngofissure operation, that should be a recommendation.

J. C. Hogg said that the question whether laryngofissure should be retained or abandoned was entirely one for the individual surgeon. Those accustomed to use radium could produce results equally good from the mortality point of view as those accustomed to do laryngofissure; but in the hands of the occasional user of radium the results were not so good.

Xanthoma of Upper Jaw.

Man, aged 39, ex-R.A.F. Admitted March 1946 with proptosis and failure of vision in right eye. X-rays showed opacity of right antrum. Exploration revealed a large encapsulated tumour expanding the antrum; this was removed. Severe hæmorrhage necessitated packing. There was still a fistula on discharge from hospital on May 1. Vision improved from 6/60 to 6/9, with disappearance of central scotoma and improvement of field. The fistula has now healed and the nose is normal.

W. H. Bradbeer said that this was one of those cases which looked formidable at first but ended happily. Xanthomata were not uncommon in the skull, especially in the petrous bone. Sometimes they were single, but there were multiple cases occurring especially in the long bones. In some cases there was also proptosis and disturbance of pituitary function, and the condition was known as the Hand-Schüller-Christian syndrome. One interesting point was that this condition tended to occur in jaundiced patients. This patient was suffering on admission from a sharp attack of benign tertian malaria, with a marked anaemia (Hb. 60%) so that it was possible he might have some hæmolytic jaundice in connexion with his xanthoma.

Blastomycosis of Nasal Mucosa (Shown by Dr. ALLEN at Mr. BRADBEER'S request).

Woman, aged 63. Treated since April 1945 for extensive blastomycotic lesions of skin. Great improvement following X-rays, potassium iodide and gold treatment. Nose shows small perforation of septum and granular condition of inferior turbinates from which the *Blastomyces dermatitidis* has, on one occasion, been identified.

H. W. Allen (Exeter) said that this was one of the first cases of the American type described in this country. The patient was first seen by him in April 1945, complaining of skin trouble affecting the cheeks and nose for a year. There were a number of minor complaints—chilblains, &c. Two or three years previously she had laryngitis. The present skin trouble started as a rash under the skin, later forming a crust; when the crust came off, a red patch was exposed and pus could be expressed. Microscopic examination of the pus showed typical blastomycetic mycelium and yeast-like double-contoured cells, which he thought he confirmed by culture. [He showed two cultures which had been obtained from the case shown and from another case of ulcerative blastomycosis; the latter had been reported on as a blastomyces, but this appeared to him to be questionable; the former was considered to show a fairly typical colony of *Blastomyces dermatitidis* with abruptly rising edge and eccentric areola.] There was no question of residence abroad in this case, and the only suggestion that this could be American blastomycosis came from the fact that American negro troops had been in the

neighbourhood where she had been staying. X-ray treatment of the face was advised, to which the skin responded readily. She responded to iodide and salicylates as well. In July 1945 the pulse-rate was 100 a minute, at which it still remained; she lost her slight pyrexia for a time, but relapses occur. The nasal condition was noted in October 1945; he thought there was a perforation of the septum. Gold treatment seemed to have improved her, or at any rate to have done her no harm. An X-ray photograph of the chest was also taken, but no complete evidence that the disease was spreading to involve the lungs had been obtained. The X-ray shows infiltration at left base as a light diffuse shadow. Mr. Bradbeer confirmed that cultures from nasal mucosa and skin were positive.

The Chairman said that he had seen three cases of blastomycosis of the chest. None of the physicians had heard of it, and in most of the recent books there was no mention of it. If he had seen this case without the history he would have said it was typical of lupus.

E. D. D. Davis said that he thought this was a case of lupus. There was a lacrimal sac infection, and there were scars on the tip of the nose and of a gland excision in the neck.

Non-malignant Stricture of Oesophagus.

Woman aged 29. History of difficulty in swallowing for about three months. Was said to have swallowed some potassium permanganate crystals. X-ray showed obstruction in upper third of oesophagus. Wassermann reaction negative. Oesophagoscopy revealed a stricture which has been dilated three times with only temporary improvement.

W. H. Bradbeer showed this case for information.

V. E. Negus said that in the treatment of this case a large oesophagoscope was required. It was important to see what the surface was like, whether the epithelium were denuded or not. Generally speaking, the result ought to be good with simple dilatation. There was a great difference in the way it was done. If bougies were put through a tight stricture one was likely to strip the epithelium. He used the dilating bag which slipped down a guide, and this bag when blown up would dilate to the size of four fingers. Possibly the stricture would have to be dilated every six months. In a small boy aged 1½ years, in whom the X-rays were identical with those in the case now shown, and in whom there was an under-development of the oesophagus at this point, as there was in congenital shortening, with lack of proper covering by epithelium, he had tried to improve matters by applying a skin graft, by making a little bag in a dumb-bell manner which could be blown up with a graft on it. He would have said that in a case like the one shown there was no radical treatment possible. Anastomosis would prove to be unsatisfactory.

Ian Robin asked how tight was the stricture.

W. H. Bradbeer said that it dilated very easily. He had dilated three times in two months and the patient only improved for a short period.

Ian Robin suggested that the patient might be instructed to pass a mercury bougie herself daily. He had a similar case which he had to dilate with olive bougies on a string, and then the patient was quite comfortable passing the mercury one, at first before every meal and now once a week.

A. J. Wright said that a good deal depended on the stage of the stricture. If there was recent injury of the oesophagus, provided the patient could be kept in a reasonable state of nutrition, the wise thing would be to leave it alone for six months or so. Interference in the acute stage of any oesophageal lesion tended to make matters worse rather than better. But it was rather difficult to say whether this was recent or not.

The Chairman said that he hoped to show the results in four cases seen in children who had traumatic strictures following the swallowing of sulphuric acid or something of that kind. The oesophagoscope had been used and a dilator passed through to determine the consistency of the stricture and then a gastrostomy had been done. The curious thing was that all these children who were able to carry on at school with a gastrostomy tube would have an ounce of milk given by the gastrostomy tube in the morning and this set up a reverse peristalsis which actually dilated the stricture, so that they could be given a soft meal, almost an ordinary meal, by the mouth in the afternoon. Two of these cases were now fit radiologically and accepted an ordinary sized oesophagoscope. The other two had so much improved that he thought the gastrostomy tube would be removed quite soon.

Section of Pathology

President—Professor W. G. BARNARD, F.R.C.P.

[July 2, 1946]

ADDRESSES GIVEN AT THE CENTENARY CELEBRATIONS OF THE PATHOLOGICAL
SOCIETY OF LONDON

The Pathological Society of London

By Professor H. R. DEAN

It is my first duty to thank you for the honour which you to-day have done to the still surviving members of the Pathological Society of London. You have asked me to tell you about the early days of the Society, but one hundred years is a long time and I can do no better than read to you extracts from the early volumes of our *Transactions* and let our predecessors speak to you in their own words.

"The establishment of a Society which should devote itself specially to the cultivation of Pathology, and render more generally available for this purpose the extensive opportunities afforded by the numerous Medical Charities of the Metropolis, had long appeared to several Members of the Profession to be desirable."

"In February 1846 several gentlemen met together and agreed upon the issue of a circular to such Members of the Profession as were known to be more particularly interested in Pathological Studies."

"A Provisional Committee of Gentlemen who had expressed their concurrence was appointed and agreed upon the issue of a Prospectus to the Members of the Profession at large, inviting their support and co-operation." This appeal met with unexpected support and on October 20, 1846, at the first Meeting of the Society there were enrolled one hundred and six members. C. J. B. Williams, M.D., F.R.S., was appointed President and B. G. Babington, M.D., F.R.S., Richard Bright, M.D., F.R.S., J. Glendinning, M.D., F.R.S., John Forbes, M.D., F.R.S., J. M. Arnott, F.R.S., Caesar Hawkins, C. A. Key, Robert Liston, F.R.S., were appointed Vice-Presidents and James Copland, M.D., F.R.S., was appointed Treasurer.

The President, the Treasurer and six Vice-Presidents were Fellows of the Royal Society and the Council "conceived that their names were too well known to the Profession to require any comment on their part, and they could not but congratulate the Society upon having secured the countenance and services of gentlemen whose high position and

distinguished attainments offered a sure guarantee for the support the Society would receive at their hands".

Among the original members were Richard Bright, Golding Bird, William Gull, William Jenner, Bence-Jones, Henry Pavey, Richard Quain and John Queckett. The first list of Honorary Members included J. C. Cruveilhier, William Stokes and C. Rokitsansky.

The First General Meeting of the Society was held on February 1, 1847, and the Council, on meeting for the first time the members at their General Meeting, thought it desirable to recapitulate the circumstances under which the Society had its origin. At this meeting it was announced that the membership of the Society had increased to one hundred and thirty, and the meetings, so the Council believed, "were generally admitted to have been possessed of a high degree of interest. They had been unusually well attended and the specimens presented had rather exceeded the number of those which could be exhibited in the time allotted to each meeting." The latter circumstance was viewed by the Council with special gratification, since they could not but regard it as establishing the correctness of their view that the Society without encroaching upon any other in existence would find a sufficient field of labour amply to occupy its time".

The Pathological Society of London was instituted for the cultivation and promotion of Pathology by the exhibition and description of specimens, drawings, microscopic preparations, casts or models of morbid parts. Rule IV governing the conduct of meetings reads as follows:

"That, in remarks made in reference to specimens exhibited, all discussions on abstract points be as far as possible avoided; and the topics of diagnosis and treatment be not introduced further than is necessary to illustrate the pathology of the subject."

In conclusion the Council had only to remark that "the future usefulness of the Society must depend on the individual exertions of the members and with this they trusted that it would eminently conduce to the advancement of that branch of Medical Science for the cultivation of which it was specially established".

The first communication was by Bence-Jones on a case of meningeal apoplexy.

At the early meetings Bence-Jones and Richard Quain were frequent exhibitors, and specimens were shown occasionally by Dr. W. Jenner. In 1850 Peter Latham became President of the Society, and W. Jenner joined the Council in 1853.

Samuel Solly had been elected to the Membership of the Society in 1847, J. S. Bristowe in 1850 and in 1852 J. Hutchinson, Jr., described as of Liverpool Street, City. Andrew Clarke was elected in 1853 and in 1854 Samuel Wilks.

During the early years of the Society the business of the Meetings was confined to the demonstration by members of specimens illustrating individual cases of disease. In 1855 Thomas Addison had published his "Essay on Disease of the Supra-renal Capsules" and at a meeting of the Pathological Society, held on January 6, 1856, Mr. Hutchinson and Mr. Bakewell reported the case of a man of 28 who had died of exhaustion after a short journey. Both supra-renal capsules were atrophied and contained calcareous concretions. At the post-mortem examination all the bystanders were struck with the remarkable brownness of the skin. Two years later Vol. IX of the *Transactions* of the Society contains the Report of a Committee of the Society which had collected and examined 12 cases of disease of the supra-renal capsules and was able to confirm Addison's observation of the association of diseases of these glands with pigmentation of the skin.

In the later fifties well-known names appear frequently in the pages of the *Transactions*. Murchison, Spencer Wells, Samuel Wilks, Christopher Heath, Bristowe and Thomas Bryant showed many specimens to the Society. In 1861 Thomas Nunneley of Leeds reported a case of rupture of a gangrenous appendix followed by peritonitis and in December of that year Jonathan Hutchinson described to the Society syphilitic ulceration of the bones of the skull with deposits on their inner surfaces: "At two points, one on the posterior half of the right parietal bone and the other on the left side of the frontal bone, were deposits of new bone, much resembling sawdust stained with blood, about as large as a crown piece."

In its first decade our Society encouraged the study of morbid anatomy rather than of morbid processes. "Our Founders had also the wisdom", as John Whitaker Hulke declared in his Presidential Address, "to recognize that no durable theory, no sufficient explanation of the processes causing structural derangement could be formed except on the solid basis of facts. The accumulation of facts was to be the Society's first care".

The foundation of our Society followed very closely upon the great discoveries then so recently made in normal histology or as it was then called "general anatomy" through "the improvement of the microscope and by the employment of methods before unknown or little used, particularly the preparation of finer and more transparent sections made possible by chemically hardening the tissues and by their differential staining".

The publication in 1858 of Virchow's lectures on cellular pathology, followed five years later by his book on the pathogenic tumours, opened a new chapter in the history of our Society. As a President of the Society remarked: "Yet, with a full appreciation of the paramount importance of established well-ascertained facts, inferences could not be altogether avoided; they would frequently force themselves upon the observer and out of them theories would sometimes arise. Who, having observed the clinical phenomena of inflammation, could avoid speculating as to its essential nature and its causes? Who familiar with the clinical courses of a cancer and a fibrous tumour and possessing some knowledge of histology could avoid the interesting question—What is it which confers on the one the endowments which we sum up under the word malignant, and gives to the other those implied by the term innocent?"

In 1869 four years after the publication of "*Die Krankhaften Geschwülste*" the Society set up a "Committee on Morbid Growths and Processes" in order "to ascertain if any and what relation exists between anatomical structure and those clinical features ordinarily regarded as malignant".

Reports on specimens from isolated cases, however, continued to constitute the chief business of the Society and in the sixties there appear in the *Transactions* names of men destined to play a great part in the development of the Medical Sciences. In 1863 Burdon Sanderson demonstrated sections of a fibro-cellular tumour of the ureter and Broadbent described a malignant tumour of the occipital bone. In 1864 Morell Mackenzie gave the first of a series of reports of tumours of the larynx and in the following year Hilton Fagge described "bronchial casts in asthma containing numerous bright rounded particles which appeared to myself and Dr. Wilks to be shrivelled nuclei".

Comparative pathology was not neglected. In 1848 Mr. Crisp exhibited six specimens illustrating disease in the lower animals including "the testicle of a ram converted into calcareous matter" and "a fungoid tumour from the eye of a canary". Other specimens exhibited to the Society were the spleen of a bull that died of splenic apoplexy, enlarged thyroid glands in young lions, diseased renal bodies in a camel, and "the colon of a sheep showing colotomy performed by a parrot".

In 1882 the Society appointed a standing Committee for Comparative Pathology and in 1887 there were communications on the diseases of vegetables.

Villemin's great discovery first published in 1865 that tuberculosis was a specific infection due to a then invisible inoculable agent transmissible from men to lower animals produced a quick response from members of the Society. In 1867 John Simon demonstrated the results of the inoculation of guinea-pigs and rabbits with material obtained from tuberculous patients and in the same year Burdon Sanderson found that the microscopical changes produced in animals by the introduction of tuberculous matter resembled closely the changes produced by sterile foreign bodies such as setons. From these experiments Sanderson drew the conclusion that the microscopical changes seen in tuberculosis were produced by the irritation of foreign bodies and that it was unnecessary to assume the existence of a living and infective virus. Three years later, however, as the result of an extensive series of experiments Sanderson was able to confirm Villemin's views by the demonstration of the close similarity of the lesions produced in experimentally infected animals with those found in the organs of tuberculous patients.

A great discussion was held under the auspices of the Society in April 1875 on the Germ Theory of Disease and it would be impossible to give here and now a summary of the arguments, for and against, put forward by Charlton Bastian, Burdon Sanderson, Jonathan Hutchinson, Murchison and other speakers. Although this discussion, carried through with great vigour on both sides, was inconclusive, communications on bacteriology became more frequent during the seventies, and in 1884 the President of the Society observed that "if all that has lately been written about these low forms of plant life be true, they would appear to take an active causative share in nearly all the ills to which flesh and blood are heir". The President added "the pages of our *Proceedings* show that our members have not been idlers in this branch of research".

In the late seventies great attention was paid to the origins and phenomena of inflammation as the relation, which at that time was not generally admitted, of

distinguished attainments offered a sure guarantee for the support the Society would receive at their hands".

Among the original members were Richard Bright, Golding Bird, William Gull, William Jenner, Bence-Jones, Henry Pavey, Richard Quain and John Queckett. The first list of Honorary Members included J. C. Cruveilhier, William Stokes and C. Rokitsansky.

The First General Meeting of the Society was held on February 1, 1847, and the Council, on meeting for the first time the members at their General Meeting, thought it desirable to recapitulate the circumstances under which the Society had its origin. At this meeting it was announced that the membership of the Society had increased to one hundred and thirty, and the meetings, so the Council believed, "were generally admitted to have been possessed of a high degree of interest. They had been unusually well attended and the specimens presented had rather exceeded the number of those which could be exhibited in the time allotted to each meeting. The latter circumstance was viewed by the Council with special gratification, since they could not but regard it as establishing the correctness of their view that the Society without encroaching upon any other in existence would find a sufficient field of labour amply to occupy its time".

The Pathological Society of London was instituted for the cultivation and promotion of Pathology by the exhibition and description of specimens, drawings, microscopic preparations, casts or models of morbid parts. Rule IV governing the conduct of meetings reads as follows:

"That, in remarks made in reference to specimens exhibited, all discussions on abstract points be as far as possible avoided: and the topics of diagnosis and treatment be not introduced further than is necessary to illustrate the pathology of the subject."

In conclusion the Council had only to remark that "the future usefulness of the Society must depend on the individual exertions of the members and with this they trusted that it would eminently conduce to the advancement of that branch of Medical Science for the cultivation of which it was specially established".

The first communication was by Bence-Jones on a case of meningeal apoplexy.

At the early meetings Bence-Jones and Richard Quain were frequent exhibitors, and specimens were shown occasionally by Dr. W. Jenner. In 1850 Peter Latham became President of the Society, and W. Jenner joined the Council in 1853.

Samuel Solly had been elected to the Membership of the Society in 1847, J. S. Bristowe in 1850 and in 1852 J. Hutchinson, Jr., described as of Liverpool Street, City. Andrew Clarke was elected in 1853 and in 1854 Samuel Wilks.

During the early years of the Society the business of the Meetings was confined to the demonstration by members of specimens illustrating individual cases of disease. In 1855 Thomas Addison had published his "Essay on Disease of the Supra-renal Capsules" and at a meeting of the Pathological Society, held on January 6, 1856, Mr. Hutchinson and Mr. Bakewell reported the case of a man of 28 who had died of exhaustion after a short journey. Both supra-renal capsules were atrophied and contained calcareous concretions. At the post-mortem examination all the bystanders were struck with the remarkable brownness of the skin. Two years later Vol. IX of the *Transactions* of the Society contains the Report of a Committee of the Society which had collected and examined 12 cases of disease of the supra-renal capsules and was able to confirm Addison's observation of the association of diseases of these glands with pigmentation of the skin.

In the later fifties well-known names appear frequently in the pages of the *Transactions*. Murchison, Spencer Wells, Samuel Wilks, Christopher Heath, Bristowe and Thomas Bryant showed many specimens to the Society. In 1861 Thomas Nunneley of Leeds reported a case of rupture of a gangrenous appendix followed by peritonitis and in December of that year Jonathan Hutchinson described to the Society syphilitic ulceration of the bones of the skull with deposits on their inner surfaces: "At two points, one on the posterior half of the right parietal bone and the other on the left side of the frontal bone, were deposits of new bone, much resembling sawdust stained with blood, about as large as a crown piece."

In its first decade our Society encouraged the study of morbid anatomy rather than of morbid processes. "Our Founders had also the wisdom", as John Whitaker Hulke declared in his Presidential Address, "to recognize that no durable theory, no sufficient explanation of the processes causing structural derangement could be formed except on the solid basis of facts. The accumulation of facts was to be the Society's first care".

On June 4, 1907, the Pathological Society was dissolved and Samuel George Shattock wrote:

"Dissoluta est jam de die quarto Junii, 1907, Societas Pathologica Londinensis, Facultas ut fieret Pathologica Societatis regiae Medicinæ, in Londino nupcr constitutæ. Quæcunque ad hanc Facultatem pertinent litteræ, conjunctim cum illis Societatis regiae Medicinæ abhinc in lucem edentur."

Cellular Pathology

By Professor G. R. CAMERON

By a strange coincidence, the life of our Society corresponds almost exactly with the rise of cellular theory, and cellular pathology in particular. Improvements in the production of microscopes made steady progress during the early years of the nineteenth century, and, in 1807, Van Deyl invented a compound microscope with achromatic objective, giving a magnification of 229. In the 1840's, large-scale microscope manufacture was going on on the Continent, and the fitting of microscopes with aplanatic and achromatic systems was a common affair. The finer structure of animal and plant life had been studied mostly by botanists throughout this period, and culminated in 1838 in the publications of Schleiden and Schwann, who gave us the famous generalization of the identity of animal and plant units of life. In the decade immediately before the foundation of our Society, the important fact was recognized that cells reproduce by direct division, though the nature of this process was not grasped until the 1870's when karyokinesis was fully worked out.

The next few years brought the discovery by Oscar Hertwig (1875) of the fusion of male and female gametes and an exact appreciation of the function of the nucleus. In this latter fundamental advance, the experimental cytologists, especially Nussbaum and Verworn, played a vital part.

From the 1890's onwards came the rediscovery of the Mendelian phenomena of heredity and their interpretation in terms of nuclear, especially chromosome, behaviour. During this period, too, the methods of physical and enzyme chemistry were applied to problems of the cell, in particular the discoveries by van't Hoff and Arrhenius, about the properties of solutions and electrolytic dissociation, whilst the elucidation of catalysis and fermentation by Berzelius and Ostwald revolutionized our notions of cell function. Long before this time, however, Graham (1861), in founding colloid science, laid the way open for a new attack on living matter. Some sort of an idea about this substance had been in existence for many years. The pioneer proto-zoologists of the eighteenth century no doubt were familiar with its cruder characteristics. Attempts at a more precise definition were made by Gruithuisen in 1811, Dujardin (1835), Purkinje (1837) and von Mohl (1846). To Purkinje we owe the term "protoplasm", the introduction of methods of fixation and staining and even a rudimentary microtome. The true place of protoplasm in the study of life was exactly stated by Max Schultze (1861) in his simplified definition of the cell as a mass of protoplasm containing a nucleus, and about the same time a broad view of the organism as a cell state was suggested by Rudolph Virchow (1858) and Brücke (1861). Whether the cell is the only living substance has since been disputed, hence it is better to speak of "cellular theory". Most biologists agree that intercellular substances and fibrils are non-living derivatives of protoplasm. Amongst such advocates was Lionel Beale, in his day a prominent member of our Society.

Shortly before the Pathological Society of London was founded in 1846, there appeared in 1845 a remarkable little book by John Goodsir and his brother, entitled "Anatomical and Pathological Observations", in which are set out some ideas about the relationship between cells and nutrition, and their importance in some pathological processes. John Goodsir clearly recognized the existence of cell territories in the organism. In this way he forestalled the better-known work of Rudolph Virchow, and it may rightly be claimed that he was one of the pioneers of cellular pathology. There is little doubt, however, that cellular pathology first came into its own with the publication in 1858 of Rudolph Virchow's "Die Cellular Pathologie". I believe Virchow's greatest contributions may be summarized as follows: Cells are the units of life and disease. They are grouped together to form territories under the control of blood-vessels. Unhealthy cells are unable to attract nutriment from their associated blood-vessels, and when this occurs, noxious ingredients pass to the blood, producing dyscrasias and metastatic disease. All disease-producing agents,

suppuration with infection. Morbid histology had supplemented morbid anatomy and morbid physiology was stimulated by the still newer science of bacteriology.

Mr. Hulke in an address to the Society pointed out that:

"The doctrine of diapedesis, the partial truth of which no unprejudiced observer can, I think, doubt, if held to the complete exclusion of all others, has never appeared to me to be free from serious difficulties. Of these I would instance three: the inconceivable numbers and rapidity in which the white blood-corpuscles must be formed in cases of extensive inflammations; the great obstacles they must have overcome in some of their wanderings to reach such resting-places in which they are sometimes found; and the singular change of endowments which the white blood-corpuscle sometimes undergoes in becoming a pus-corpuscle. In illustration of the first of these difficulties, let me instance the histological phenomena of erysipelas. Here the whole subcutaneous areolar tissue of a limb will in a few hours become stuffed with leucocytes, for the enumeration of which billions were too small a unit. How difficult is the conception that the formation of white blood-corpuscles could have been so augmented and accelerated as to have, in addition to the normal physiological requirements, supplied these countless swarms of emigrants. Other instances of such wonderful journeys might be cited, but those which I have adduced may suffice to show that implicit credence in travellers' tales is not always easy. Why the white blood-corpuscle, become pus-corpuscle, should lose its pristine innocence, and acquire so virulent a nature, as we know it sometimes has, may find its explanation in the observation made by Hueter, that the corpuscles of septic pus contain within them Schizomycetes.

"During the whole existence of our Society no theory has arisen that in its practical bearings can rank in importance with one which in the present decade has gained so many adherents. I mean the doctrine which teaches that the inception and maintenance of the inflammatory process are due to the influence of those living agents which appear to be inseparably connected with the process of putrefaction—a doctrine which has here been so ably expounded by Sir Joseph Lister, and which one of its ablest and most thoroughgoing continental advocates, the late Professor Hueter, whose early death all must deplore, embodied in the aphorism, 'Without Schizomycetes no sepsis—without sepsis no inflammation'."

In conclusion I cannot do better than quote a few sentences from the Presidential Address of Samuel Wilks delivered on February 19, 1881:

"I have always considered that the glory of this Society has lain in its cultivation of morbid anatomy. If this were not so, wherefore the need of its existence? Before its foundation other Societies were in full force, one of their functions being the discussion of questions of pathology, and to them the right still remains; but the opportunity was needed by which those engaged in the new science of pathology could organize their work and bring together facts, so as to place on a surer foundation the more substantial and material data on which so many morbid processes depend."

"Why so great devotion to pathology? Does it help us to cure the sick? Can it assist us in alleviating the sufferings of our fellow-creatures, which is the great object of our calling? Or, does not pathology keep far in advance of therapeutics? For my part I have not the slightest feeling of sympathy with these questions, for I believe that discoveries in pathology and therapeutics always go hand in hand. Of course, I know there is a doctrine which maintains that therapeutics has a basis on its own, and physiology and pathology may be altogether ignored. I need not remind you, gentlemen, who are engaged in scientific work, that such considerations as ulterior and practical results are not worthy of you. A scientific man is a worker for truth, and, in my experience, if he sees any other object before him than the immediate result of his investigations, or if he be working by any other light than the 'siccum lumen', of which Bacon speaks, he will miss his mark. The discovery of a new fact must bring with it good, although the scientific man works for truth alone, and feels that knowledge is its own reward."

"It would, indeed, be easy to show the enormous accumulation of knowledge which has arisen from a simple inspection of the dead, and we are proud to think that much of this is contained in our *Transactions*."

"In conclusion, let me say that our Society stands out prominently in the history of medicine as having taken a large share in the cultivation of one of its most important branches. It has made constant progress, and has never slackened in its work, and if you now, gentlemen, maintain it in the same path during my two years of office I shall be more than content."

Cellular pathology originated from the general study of the nature and origin of living things. Its future lies in maintaining this close connexion and fundamental advances will come only so long as this relation is preserved.

Chemical Pathology

By Professor E. C. DODDS

THE growth of chemical pathology has been characterized by great irregularity right from its inception. When systematic organic chemistry had been placed on a firm foundation by the organic chemists of the early part of the last century, almost without exception they worked on biological products. One only thinks of names of people like Liebig, Hoppe-Seyler and others to conjure up immediately the work on proteins, carbohydrates, hemoglobin, &c. There is no doubt that these men can be regarded as the originators of the interest in chemical pathology. By the middle of the last century, however, the growth of synthetic organic chemistry had developed, with the result that organic chemists of the day deserted the study of the natural products for the much more fascinating problems presented by this new science of organic chemistry.

By the end of the last century and the dawn of this one, chemical work in pathology was really confined to very elementary examination of the urine, faeces, gastric juices, &c., and the examination of the blood for chemical constituents was largely a research problem. No notable developments in the subject occurred in this country for a very long period due mainly to the lack of suitable methods. Very rapid developments were made in America, however, from 1912 onwards, when Folin began to publish the result of his researches on colorimetric methods. He realized that if a number of blood constituents were to be estimated, then some form of common filtrate must be prepared from a single specimen on which it would be possible to estimate urea, sugar, uric acid, non-protein nitrogen, &c. This he succeeded in doing by the introduction of the well-known tungstic acid method of precipitation. He developed colorimetric techniques for the estimation of practically every known constituent of blood. These methods were not used in this country until years after publication for three reasons: (1) The main developments were published during the 1914-1918 war when there were more urgent and immediate problems to attend to. (2) There existed a violent prejudice against colorimetric methods amongst British biological analysts. They regarded the colorimeter as a somewhat immoral instrument which enabled people to take a short cut to results which should only be arrived at by an elaborate technique performed by an expert. Finally, it must be admitted that there was a third reason, and that was the extraordinary inaccuracy of many of Folin's publications. Whilst he was a meticulous worker, he was an extremely careless writer, with the result that if one performed a method as he described it, the chances were that some untoward event would intervene such as a heavy precipitate or an unexplained colour which rendered the determination impossible. I remember myself struggling with a uric acid method in which, just before one made the colorimetric comparison, a dense white precipitate appeared, rendering comparison quite impossible. Unfortunately Folin was that type of genius who did not reply to letters. I always remember on my first visit to the States going to him and questioning him about this determination of uric acid. He replied imperturbably that he did not use that reagent at all now, and gave me an entirely different one that worked perfectly. By 1920, however, a number of people had struggled with Folin's methods and had actually got them to work and they are now the basis of the methods utilized in chemical pathology.

I would earnestly suggest that a greater number of posts be made for chemical pathologists in any future planning and that these posts should be independent, collaborating on terms of equality with the clinicians and the pathologists. To my mind it is a retrograde step to regard the chemical pathologist as an assistant to the pathologist because I am certain that if this attitude is persisted in, then the best type of biochemist will not be attracted to chemical pathology. Again I would like to suggest for consideration that the biochemist who takes up chemical pathology need not necessarily possess a medical qualification. It seems to me much more essential that he should have a first-class knowledge of chemistry and biochemistry and that he can leave the medical knowledge on the one hand to his clinical colleagues and on the other hand to his pathological colleagues.

except those which arise primarily in the blood, are derived from altered metabolism of cells. Cells are disturbed in a number of ways. Disturbed function, for instance, leads to exhaustion and fatigue; disturbed nutrition to hypertrophy, degeneration and inflammation; whilst if the formative function of cells be upset, there follows hyperplasia, pus formation, tuberculosis or neoplasms.

Virchow recognized the importance of the cell in inheritance, and his famous dictum "*omnis cellula e cellula*" is as important to genetics as it is to cellular theory in general. Virchow, however, was insistent that the discovery of causes of disease does not clear up the nature of such diseases. Throughout his long life, he returned to this idea and continually stressed the need for further information about the nature of protoplasm and its response to injury.

In this limited time I cannot do more than touch on a few problems which cellular pathology has elucidated. Amongst these of first importance is the question of inflammation. Blood cells were recognized soon after the invention of crude microscopes by Pisa (1656), Swanmerdam (1658), Malpighi (1661-1665), Leeuwenhoek (1687). In 1824, the French biologist Dutrochet described the migration of white corpuscles through the walls of blood vessels, but he gave no reason for this. It remained for the British investigators, Augustus Waller and William Addison (1839-1846), to show that migration of white cells occurred from the vessels of an injured part, whilst, in 1850, Thomas Wharton Jones noted that granular leukocytes appeared in large number in wounds, moving out of the regional blood vessels by means of intrinsic movements. Wharton Jones described the margination of such corpuscles and he also studied the formation of fibrous tissue. The investigations of Julius Cohnheim crowded into an all too short life resulted in a dynamic idea of the process and gave us, with few exceptions, our modern views on inflammation. The controversies which sprang up around Cohnheim's work added much exact information about proliferation of tissue cells, including the tumour cell.

Closely related in time was the study of phagocytosis, and here again we note the important part played by the biologists. Virchow (1852) had seen red blood corpuscles inside other cells and had attributed this to mechanical pressure, a view which stultified the original observations of cellular pathologists for some years. Ernst Haeckel, in 1858, noted that indigo granules were taken up by anaëboid cells of gasteropods. About ten years later, von Recklinghausen, Ponfick and Langhans showed that carmine particles introduced into the circulation of animals were ingested by cells in the spleen, bone-marrow and liver, and indeed a few years before Preyer (1864) actually watched blood cells taking up particles. Robert Koch, in 1876, found anthrax bacilli in the round cells of frogs infected with that organism, and Grawitz, in 1879, described similar ingestion of a fungus from the lily of the valley. In an apparently forgotten observation, Roser, in 1881, suggested that immunity of plants and animals partly depends on the property of their contractile cells of ingesting micro-organisms, but it remained for Metchnikoff to establish the phagocytosis theory as we now know it.

It is thus possible to recognize three stages in the hundred years of cell theory and cellular pathology: (1) The pre-cellular period which overlaps into our period, when many of the fundamental observations about cells were made by isolated workers without any clear idea of a connecting link. (2) The cellular period, a stage of almost pure morphology with little emphasis on protoplasm. (3) A period of physico-chemical investigation, with more and more attention being given to the nature and function of protoplasm. Glimmerings of quantitative study appeared at this stage, which correspond with the rise of biochemistry and biophysics.

I believe we are now passing into a fourth stage, which might be called the "sub-microscopic period", in which as the result of the work of Astbury, Bernal, Schmitt and Schmidt, we are coming to think of protoplasm in terms of giant molecules and mono-molecular surface films and their physico-chemical properties, governed by molecular arrangements. This stage is progressing from a relatively simple colloid chemistry to the involved considerations of high polymer chemistry. For its development the most exacting requirements in scientific training will be necessary, for the methods of such special fields as polarization optics, X-ray crystallography and electron microscopy, together with an appreciation of the range of biology, would seem to be essential in the future training of the investigator into protoplasmic reactions.

At present, the only way out of this deadlock appears to be through the formation of teams comprising physicists, biologists and plant and animal pathologists. I doubt very much whether any of us could hope to cope with this type of research without a radical revision in our medical education.

the Middlesex Hospital. The method ultimately devised for obtaining large concentrates has now been adopted in America.

With these large concentrates which we prepared, Pollard was able to study the chemical nature of these viruses, showing that they contain phosphorus to such extent that they consist in a large part of nucleo-protein.

Filtration.—Another important step forward in the study of viruses of course was by ultra-filtration with specially prepared collodion membranes and I would like to draw attention to the important work in this respect which was carried out at the National Institute for Medical Research by Elford and others; with his series of gradocol membranes of different porosities he was able to determine actually the size of many viruses.

Growth.—The failure to grow viruses on ordinary medium was found to be due to the fact that viruses live and multiply inside the tissue cells and require to get their food by a parasitic process. As you all know this growth can now be promoted and watched in the allantoic cell of the growing chick embryo, a fact of great importance in the preparation of vaccines.

Vaccinia.—In dealing with individual virus infections it is right that the first place should be given to vaccinia on which so much work has been done in the early part of last century. Since then there has been great improvement in the preparation and purification of vaccinia virus and in this respect I must refer to Copeman who introduced the process of mixing the lymph with glycerine and then freezing to get rid of the contaminating bacteria, thus reducing to an almost infinitesimal point one of the most serious drawbacks to vaccination, the risk of secondary infection, and in the demonstration of elementary bodies in smallpox vaccine, the names of Mervyn Gordon and Ledingham must also be mentioned.

Another important discovery in this country with regard to vaccination was the recognition of post-vaccinal encephalitis in which Professor Turnbull and I worked in collaboration and definitely showed it to be a specific lesion of the central nervous system. In regard to other neurotropic viruses, I might mention here the studies carried out by Mervyn Gordon and others on the nature of this devastating disease of children, poliomyelitis. Much work was also done in the 1914-18 war on epidemic encephalitis by Marinesco, Hall, myself and others, when it was demonstrated to be of a virus nature—though other causes had been attributed, as for instance, a form of botulism, a rather amusing one, suggested by an old lady was that it was due to the bite of the bot fly!

Bacteriophages.—One of the most outstanding discoveries ever made in the virus field was made by a member of this Section, Professor Twort, who discovered the bacteriophage. Though much discussion has centred around the actual nature of the bacteriophage, the general opinion now is that it is a virus which is capable of living inside bacteria and destroying them. It is interesting to note that I was working in the same laboratory with Professor Twort at the London Hospital when he made his great discovery, and I was then able to follow the various stages of this discovery and to say that very early on he considered that it should be regarded as a virus. Twort's original paper contains all the essential features of this important and significant reaction. He observed that staphylococcal cultures obtained from vaccinia underwent a peculiar type of degenerative change due to the action of the bacteriophage. This simple observation has provided us with many new facts with regard to viruses, their size, function and behaviour and in addition has provided us with a means by which we can identify different strains of *Bact. typhosum*, staphylococci and other organisms. Though some still hold that this bacteriophage is really a self-catalytic breakdown, the general view is that bacteriophages are viruses and definitely particulate.

Influenza.—Up to the time of the last pandemic of influenza (1917-1918), the influenza bacillus of Pfeiffer held the field as the chief aetiological agent of epidemic influenza. But the failure to demonstrate regularly the presence of this organism in the catarrhal secretions in this pandemic of influenza raised some doubt as to its real aetiological significance. Following this, with the aim of demonstrating the presence of a virus, extensive researches were taken up in this country and in America, with the result that Laidlaw, Andrewes, and W. Smith were successful in demonstrating a filter-passing virus in certain cases of epidemic influenza and this work has been confirmed throughout the world and it has been shown that there is more than one strain of virus influenza and furthermore that the complete relationship of the bacillus to the virus is still problematic.

[Thus for instance, in pig influenza it is known that the *haemophilus* bacillus as well as the virus does play an important part in the epidemic. The success of Laidlaw and Andrewes was that they were able to transmit the disease to mice. The fact that one can infect mice by nasal instillation gave facilities for obtaining large amounts of antigen

The type of problems to be tackled come under two headings, first, the performance of routine investigations on patients, such as urea clearance tests, calcium balances and similar procedures, and secondly, and more important, the actual search for new chemical substances in the various secretions of the body. A careful investigation of body fluids will undoubtedly reveal the presence of new substances of the greatest interest both to the chemist from the purely chemical angle and to the biochemist and pathologist.

In the year 1927, for example, the average biochemist would have said that all the urinary constituents were known and that the chemical investigation of this fluid would certainly not lead to any new discoveries. Now we know that up to 1927 enormous quantities of fascinating steroid substances such as œstrone had been steadily poured down the drain in the urine of pregnancy without anyone suspecting their presence. It may well be that as advances are made in the future we shall be still more astonished at what we have been throwing away. It is in this field in particular that we must attract the non-medical chemist and biochemist.

Viruses

By Professor J. McINTOSH

THOUGH never an actual member of the old Pathological Society of London, I have attended some of the meetings in Hanover Square, having been as it were led by the hand by my old chief Professor William Bulloch, so in that respect I may be regarded as a link between the new and the old when such a subject as the theory of the spontaneous generation of life had not died out.

The study of viruses is a relatively new branch of pathology, as the demonstration of the existence of a filter-passing microbe is only some 50 years old, only half the age of this Society, but during the last few years the strides made in the discoveries on viruses and their nature have been enormous, in fact one might almost say that it has become a science of its own.

In the first few years of this century when I was a student, no textbook index included the term "virus" or "virus disease", at any rate certainly not in its present meaning. The discovery of viruses is attributed to Ivanowsky in 1892 who stated that the cause of the disease of plants known as "tobacco mosaic" was due to a filter-passing microbe. His idea was confirmed by Loeffler and Frosch, who transmitted by bacteria-free filtrates the infection of foot and mouth disease, a disease of the utmost importance to cattle breeders in this country and a subject on which much work has since been done.

We now attribute at least 30 diseases of man to viruses—almost as many as those caused by bacteria. The time at my disposal, however, does not allow me to review completely the development of this subject but I would like to deal with the more important discoveries in which members of this Society have played an important part and in which advances were made not only in the technique of approach to the study of virus disease but many new viruses were actually discovered.

The failure to demonstrate viruses morphologically on the ordinary microscope and the failure to grow them on ordinary bacteriological medium gave scope for ingenuity in the development of new processes and procedures for their demonstration, such as in microscopy, centrifugalization, filtration, cultivation in eggs for the discovery of new virus infections.

Microscopy.—The size of viruses necessitated the design of more powerful microscopes.

This was achieved by improving the resolution by the use of ultraviolet rays and special quartz lenses. In this aspect of the work the name of Barnard and his ultraviolet microscope takes a prominent place. Now we have the electron microscope which is capable of almost any degree of magnification and resolution.

The minuteness of viruses had also necessitated a new scale of measurement and for this purpose the micromillimeter or millimicron ($\frac{1}{1000}$ mm.) is used.

Ultra-centrifuge.—For the study of viruses and obtaining large amounts of virus concentrates it soon became apparent that the ordinary bacteriological centrifuge was not capable of providing the gravimetric pull necessary to sediment the virus particles for the purpose of (1) studying the virus concentrates and (2) for the determination of the size of the particles. In this respect one might mention the work carried out by Slesinger at the National Institute for Medical Research and by myself and Selbie at

Section of Ophthalmology

President—P. E. H. ADAMS, F.R.C.S.

[April 11, 1946]

Retinal Periphlebitis.—A. SEYMOUR PHILPS, F.R.C.S.

A. D., aged 42. Lance Corporal.

History.—1945: Vision of the right eye failed partially for a few days and then recovered. He did not see an oculist. No further trouble until March 1946 when the right eye failed suddenly and completely.

On examination.—There is a total R. vitreous hæmorrhage. R. vision is perception of light.

L. eye: Vision 6/9. There are many red cells in the vitreous. On full dilatation of the pupil it is seen that the peripheral retinal veins are thrombosed, and surrounded by hæmorrhage and some exudate. There is also some macular œdema.

The blood in the L. vitreous is increasing slowly, and it seems only a matter of time before this eye also becomes blacked out. The diagnosis seems to be retinal periphlebitis, and he is shown here for the advice of this meeting regarding cause and treatment. All tests have proved negative.

Mr. O. Gayer Morgan said that he had had two similar cases, one that of a man in the R.A.F. who had noticed loss of vision in one eye, for the first time, when he landed in Normandy. When he first saw him in England about a week later one eye was completely destroyed. Presumably there was a large hæmorrhage and detachment. The other eye had a very similar condition to that in Mr. Philps' case—very marked periphlebitis, little hæmorrhages scattered about the fundus, not all peripheral, and it was difficult to tell whether those in the periphery were slightly dilated vessels or small hæmorrhages. The man had gradually settled down with one good eye; he had been on a very light job and was carefully watched. Every single investigation was negative. He first saw the case over a year ago, and the man still had about 6/5 vision in the good eye. The hæmorrhages were smaller, but the periphlebitis was still fairly obvious.

His second case was of a similar type, but this young man was very lethargic, with a "fishy" sort of cold blue hands and cold feet. He had chilblains, and, apparently, his general circulation was poor. Otherwise, again, all investigations were negative. The signs were all in the mid-periphery; there was nothing in the central part of the fundus. One could map out exactly where the changes in the vessels occurred; they were in an area which was mid-peripheral. There had been two hæmorrhages in one eye and three in the other. He carried out a surface diathermy over the area of vascular change, all the way round in both eyes, so that there was a band of grey reaction in the fundus in the area of the change. This was nearly four years ago, and there had been no further hæmorrhage. The treatment did not seem to have affected the eye in any way; there was no alteration whatever in tension.

Mr. E. F. King said that it seemed that these cases were rather more commonly seen in Service patients; he did not know whether that was the experience of others, but certainly he had had several of them in the Army. One case he might mention as an example of what not to do. On the advice of a physician he gave the man dicoumarin, a drug which was cumulative in its effect. There was no result for the first three days, and then the patient had the most violent hæmaturia. It was quite uncontrollable, and only by a series of blood transfusions was the man's life saved. The drug had no effect whatever on the eye condition.

Lieut.-Colonel C. Dee Shapland agreed with Mr. King that this type of case was not unusual in the Army. The condition appeared to be a periphlebitis affecting the smaller retinal veins more especially towards the fundus periphery and associated with multiple thromboses and hæmorrhages. He had had all his cases admitted to hospital and thoroughly investigated but no definite ætiological factor had been discovered. One case was treated with systemic penicillin but without any appreciable effect and others in whom sulphonamides had been employed had also shown no improvement.

Mr. Nigel Cridland said that he had had one case rather similar in type. When he found that the man had a low blood-calcium level he put him on parathyroid and on extra supplies of milk. Whether it was a case of cause and effect he could not say, but there were no further hæmorrhages for five months. He obtained the improvement with doses of parathyroid which kept the blood-calcium level up to about 10.5 mg. per 100 c.c.

Mr. F. R. Neubert said that there were a number of cases in the R.A.F., one of which had been in his hands for quite a time. This man was given tuberculin treatment, and he believed it was seven months since his last hæmorrhage. The patient had asked to be allowed to continue with the treatment because he thought it was doing him good.

The Chairman (Mr. F. A. Williamson-Noble) said that Mr. Philps had been given a variety of suggestions on which he could act. It would be interesting if later he could report what had happened as a result of the method of treatment adopted.

which have been tried out as a preventive vaccine. It is too early yet to make any definite pronouncement on the value of such inoculations.]

Psittacosis.—It had been recorded for some time that the outbreaks of a peculiar type of influenzal-typhoid type of disease was limited to those who had contact with parrots and similar birds of that species. Bedson and Weston in 1930 showed that this infection could be transmitted to budgerigars and mice and demonstrated the presence of virus-like bodies in the infected tissues, thus establishing the virus nature of the disease.

Typhus fever.—With regard to typhus or rickettsial diseases I would like to mention that Professor Matthew Hay, one of my old teachers, was the first to demonstrate clearly that in the outbreak which occurred in Scotland, the disease was spread by lice. A considerable amount of work was done in this country with regard to the relationship of lice to typhus fever and in this respect Bacot and Arkwright in 1923 threw much light on the mechanism by which lice spread the infection. I myself derived intense amusement one evening in watching them perform the tricky operation of infecting lice by rectal injections of *Rickettsia*, a feat of great delicacy—if not of an æsthetic kind.

The virus theory of cancer.—I have left to the last the relationship of the virus to human cancer, because this is still problematic, though many papers have been read in this Section on virus tumours in animals, such as the Rous sarcoma of fowls and the Shope papilloma, by Gye, Andrewes, Peacock, Selbie and myself, particularly on the relationship of carcinogenesis to virus tumours—a problem still not yet completely worked out and which is one of the problems of utmost importance which we have to tackle.

Chemotherapy.—So far chemotherapy has not been so successful against virus infections as against bacterial ones, except perhaps in the case of the *Rickettsial* group. But I might mention that some measure of success has been claimed by Findlay with regard to the use of sulphonamides in lymphogranuloma inguinale and by Bedson with penicillin against psittacosis. That chemotherapeutic remedies are not so successful against viruses is probably due to the differences in the metabolic activities of bacteria and viruses.

CONCLUSION

In conclusion might I say what an amazing new world of the infinitely small has been laid bare in the last half century and I have no hesitation in saying that this period of virus study rivals the golden age of bacteriology of Pasteur and Koch. I am intensely happy to have watched this development and to have taken some part in it and it has given me great pleasure to lay before this Society this review of the last fifty years in which the whole of the energies have been concentrated to the good of mankind and not to his destruction.

Section of Ophthalmology

President—P. E. H. ADAMS, F.R.C.S.

[April 11, 1946]

Retinal Peripblebitis.—A. SEYMOUR PHILPS, F.R.C.S.

A. D., aged 42. Lance Corporal.

History.—1945: Vision of the right eye failed partially for a few days and then recovered. He did not see an oculist. No further trouble until March 1946 when the right eye failed suddenly and completely.

On examination.—There is a total R. vitreous hæmorrhage. R. vision is perception of light.

L. eye: Vision 6/9. There are many red cells in the vitreous. On full dilatation of the pupil it is seen that the peripheral retinal veins are thrombosed, and surrounded by hæmorrhage and some exudate. There is also some macular œdema.

The blood in the L. vitreous is increasing slowly, and it seems only a matter of time before this eye also becomes blacked out. The diagnosis seems to be retinal peripblebitis, and he is shown here for the advice of this meeting regarding cause and treatment. All tests have proved negative.

Mr. O. Gayer Morgan said that he had had two similar cases, one that of a man in the R.A.F. who had noticed loss of vision in one eye, for the first time, when he landed in Normandy. When he first saw him in England about a week later one eye was completely destroyed. Presumably there was a large hæmorrhage and detachment. The other eye had a very similar condition to that in Mr. Philips' case—very marked peripblebitis, little hæmorrhages scattered about the fundus, not all peripheral, and it was difficult to tell whether those in the periphery were slightly dilated vessels or small hæmorrhages. The man had gradually settled down with one good eye; he had been on a very light job and was carefully watched. Every single investigation was negative. He first saw the case over a year ago, and the man still had about 6/5 vision in the good eye. The hæmorrhages were smaller, but the peripblebitis was still fairly obvious.

His second case was of a similar type, but this young man was very lethargic, with a "fishy" sort of cold blue hands and cold feet. He had chilblains, and, apparently, his general circulation was poor. Otherwise, again, all investigations were negative. The signs were all in the mid-periphery; there was nothing in the central part of the fundus. One could map out exactly where the changes in the vessels occurred; they were in an area which was mid-peripheral. There had been two hæmorrhages in one eye and three in the other. He carried out a surface diathermy over the area of vascular change, all the way round in both eyes, so that there was a band of grey reaction in the fundus in the area of the change. This was nearly four years ago, and there had been no further hæmorrhage. The treatment did not seem to have affected the eye in any way; there was no alteration whatever in tension.

Mr. E. F. King said that it seemed that these cases were rather more commonly seen in Service patients; he did not know whether that was the experience of others, but certainly he had had several of them in the Army. One case he might mention as an example of what not to do. On the advice of a physician he gave the man dicoumarin, a drug which was cumulative in its effect. There was no result for the first three days, and then the patient had the most violent hæmaturia. It was quite uncontrollable, and only by a series of blood transfusions was the man's life saved. The drug had no effect whatever on the eye condition.

Lieut.-Colonel C. Dee Shapland agreed with Mr. King that this type of case was not unusual in the Army. The condition appeared to be a peripblebitis affecting the smaller retinal veins more especially towards the fundus periphery and associated with multiple thromboses and hæmorrhages. He had had all his cases admitted to hospital and thoroughly investigated but no definite ætiological factor had been discovered. One case was treated with systemic penicillin but without any appreciable effect and others in whom sulphonamides had been employed had also shown no improvement.

Mr. Nigel Cridland said that he had had one case rather similar in type. When he found that the man had a low blood-calcium level he put him on parathyroid and on extra supplies of milk. Whether it was a case of cause and effect he could not say, but there were no further hæmorrhages for five months. He obtained the improvement with doses of parathyroid which kept the blood-calcium level up to about 10.5 mg. per 100 c.c.

Mr. F. R. Neubert said that there were a number of cases in the R.A.F., one of which had been in his hands for quite a time. This man was given tuberculin treatment, and he believed it was seven months since his last hæmorrhage. The patient had asked to be allowed to continue with the treatment because he thought it was doing him good.

The Chairman (Mr. F. A. Williamson-Noble) said that Mr. Philips had been given a variety of suggestions on which he could act. It would be interesting if later he could report what had happened as a result of the method of treatment adopted.

Bilateral Aphakic Retinal Detachment (A case showing unusual restoration of central vision following reposition).—Lieut.-Colonel C. DEE SHAPLAND, R.A.M.C.

Spr. J. A. A., aged 37, was admitted to the Military Hospital, Shenley, on June 30, 1945. His sight was known to have been defective in both eyes in early childhood, but he was not seen by an ophthalmic surgeon until 1923, when, at the age of 15 years, he came under the care of the late Mr. J. A. Valentine who found lamellar cataract in each eye, the visual acuity of the right eye with -5.0 sph. being $6/9$ and that of the

left $6/18$ with -8.50 sph. In 1929 the vision of the right eye with $\frac{-7.5}{-1.0} \downarrow 90^\circ$ had

fallen to $6/12$ and that of the left with -12.0 sph. to $6/36$. Operation was recommended and in that year discission of the left cataract was performed followed six months later by a similar operation on the right, each eye being needled three times. In 1931, the sight of the left eye failed, a retinal detachment was found and was operated upon without success.

In November 1940 the visual acuity of the right eye was $6/60$ unaided, with aphakic correction $6/6$, and that of the left eye no perception of light. Despite this he was called up, went to North Africa in November 1942 and to Italy in October 1943. On April 4, 1945, he walked into a lamp-post in the blackout and sustained a laceration of the right lower eyelid and was admitted to hospital for five days. The ophthalmologist reported—R. aphakia, fundus normal, vision with $+5.0$ sph. = $6/9$. L. tremulous iris, complete detachment with degenerate retina.

On June 18, 1945, J. A. A. noticed a mist over his right eye which rapidly increased and the next day he reported sick. An extensive retinal detachment was found, he was evacuated by air to the U.K. and was first seen by me on July 5. An apparently total detachment of the retina in the right eye was present with a small oval hole supero-nasally some 4 d.d. from the ora, vision being reduced to perception of light only (fig. 1). The case appeared hopeless but the patient agreed to surgical treatment and was operated upon on July 12, 1945—5 surface applications followed by 3 needle punctures over the site of the retinal hole, no muscle being detached. The retina went back and he was discharged from hospital on September 9, 1945, with a full field and the remarkably good central vision of $6/12$ and J. 2 with correction (fig. 2). On April 3, 1946,

FIG. 1.—Spr. J. A. A. Appearance of right fundus, July 5, 1945. An apparently total detachment of retina with small oval hole at 2.30 o'clock 6 mm. behind ora serrata.

FIG. 2.—Spr. J. A. A. Visual field to 1° white target September 9, 1945. Central vision with $\frac{+4.0}{+1.5} \downarrow 165^\circ$ = $6/12$ and $+3.5$ added = J. 2.

visual acuity had improved to $6/9$ with aphakic correction $\left(\frac{+4.25}{+1.25} \downarrow 150^\circ \right)$ and with $+3.5$ added he read J. 1 with ease.

This case has been shown as an example of a remarkable restoration of central vision in an apparently total detachment of the retina. The wider question of the advisability of needling of both eyes in cases of congenital cataract is also raised. The incidence of a subsequent retinal detachment following discission of the lens is high. In a paper (1934), I stated that it was probably in the neighbourhood of 10%, and occurred after an average interval of twenty-five years; I suggested that one eye only be needled in childhood, its fellow being left in reserve unless the cataract were so dense as to make

the eye, if unoperated, of little value. In this respect an acuity of 3/60 was suggested as a useful visual standard rather than the 6/18 to 6/24 which had hitherto been fairly generally adopted.

REFERENCE

SHAPLAND, C. DEE (1934) *Trans. Ophthalm. Soc. U.K.*, 54, 176.

The Chairman said that the question of needling was constantly arising and it was useful to have the figures given by Colonel Shapland. He recently had a case of this kind, and wished he had known of Colonel Shapland's experience, but he advised that the patient should have only one eye needled. There was the question of amblyopia in the eye which retained the opaque lens. The patient was a child aged 2 years.

Recurrent Proptosis Due to Cavernous Lymphangioma of the Orbit.—EUGENE WOLFF, F.R.C.S.

B. E., female, aged 27.

History.—This case is described in the *Trans. Ophthalm. Soc. U.K.* (1932) 52, 298. She has had a number of attacks of recurrent proptosis, the first apparently being at the age of 4 years. The proptosis comes on quite suddenly, the eye being very prominent in a few hours. This is accompanied by a little fever. It takes some six weeks as a rule for it to go back to normal and finally there is some enophthalmos. The disc is now atrophic and there is extensive macular degeneration probably due to interference with the ciliary arteries. She has just had another attack.

The actual diagnosis in this case was made by the removal of a small tumour near the left eyebrow which proved to be a cavernous lymphangioma.

On examination.—All investigations negative. *Treatment.*—Nil significant.

Comment.—Cavernous lymphangioma undergoes recurrent attacks of swelling, most commonly due to inflammation, more rarely to hæmorrhage. Now this swelling is obvious on the surface of the body; in the orbit, however, it manifests itself as a proptosis. Also these attacks of swelling in lymphangioma elsewhere tend to subside spontaneously. In the orbit this would be seen as a disappearance of the proptosis.

Thus, a recurrent attack of inflammation would, in a lymphangioma of the orbit, manifest itself clinically as a recurrent proptosis, and the final fibrosis, no doubt affecting the orbital fat as well, would result in enophthalmos.

Mr. Seymour Philips asked whether Mr. Wolff had had the optic foramen X-rayed.

Mr. Wolff replied that that had not yet been done, but that he would certainly carry out this examination.

Inverse Graphism, Mirror Writing and General Behaviour of Twins.—NOËLLE CHOMÉ, M.B. Lausanne.

Abstract.—Two boys aged 7 years, but mentally aged about 5 years. These children write, draw and read South-North, in other words putting people and letters upside down. One of the twins is often left-handed.

A film taken in the school demonstrating their behaviour was shown.

Mr. Victor Purvis remarked that the two children who were the subjects of this communication would be of interest to physiologists and psychologists for a long time to come. He looked forward to the time—perhaps twenty years hence—when Dr. Chomé would come and tell them the after-history. He gathered that there was a distinction between mirror writing and north-and-south writing. Mirror writing was fairly common. It was found in left-handed children. North-and-south writing and reading characterized few of their patients and he only remembered one case in the out-patients' department where an old lady read for the whole of the morning session, holding the reading matter upside down.

The Optical Control of Sharp Ophthalmic Instruments

By J. F. KAYSER and JOHN FOSTER

INTRODUCTION (J. F.)

SINCE Heinrich Schmidt included in his paper, "Der Einzügige Starschnitt" (*Z.f. Augen.* 1911, 25, 154), a dispassionate estimate of British cataract knives, their reputation has been paramount. Many American oculists used to spend their entire duty-free import allowance on them in prewar days. Of recent years, Swiss knives have gained a good reputation also.

In judging the sharpness of a cataract knife by its operative performance, allowance must be made for variations in scleral toughness, the effects of sterilization, lack of skill in the rapidly changing theatre staff of a training school, and the angle of attack adopted by the operator.

Due allowance having been made for these factors by 1940, one of us (J. F.) had become convinced that the lack of uniformity in performance was due largely to the failure of the trial drum to eliminate defective units. He therefore asked the Master

Bilateral Aphakic Retinal Detachment (A case showing unusual restoration of central vision following reposition).—Lieut.-Colonel C. DEE SHAPLAND, R.A.M.C.

Spr. J. A. A., aged 37, was admitted to the Military Hospital, Shenley, on June 30, 1945. His sight was known to have been defective in both eyes in early childhood, but he was not seen by an ophthalmic surgeon until 1923, when, at the age of 15 years, he came under the care of the late Mr. J. A. Valentine who found lamellar cataract in each eye, the visual acuity of the right eye with -5.0 sph. being $6/9$ and that of the left $6/18$ with -8.50 sph. In 1929 the vision of the right eye with $\begin{smallmatrix} -7.5 \\ -1.0 \end{smallmatrix}$ \downarrow 90° had

fallen to $6/12$ and that of the left with -12.0 sph. to $6/36$. Operation was recommended and in that year discission of the left cataract was performed followed six months later by a similar operation on the right, each eye being needled three times. In 1931, the sight of the left eye failed, a retinal detachment was found and was operated upon without success.

In November 1940 the visual acuity of the right eye was $6/60$ unaided, with aphakic correction $6/6$, and that of the left eye no perception of light. Despite this he was called up, went to North Africa in November 1942 and to Italy in October 1943. On April 4, 1945, he walked into a lamp-post in the blackout and sustained a laceration of the right lower eyelid and was admitted to hospital for five days. The ophthalmologist reported—R. aphakia, fundus normal, vision with $+5.0$ sph. = $6/9$. L. tremulous iris, complete detachment with degenerate retina.

On June 18, 1945, J. A. A. noticed a mist over his right eye which rapidly increased and the next day he reported sick. An extensive retinal detachment was found, he was evacuated by air to the U.K. and was first seen by me on July 5. An apparently total detachment of the retina in the right eye was present with a small oval hole supero-nasally some 4 d.d. from the ora, vision being reduced to perception of light only (fig. 1). The case appeared hopeless but the patient agreed to surgical treatment and was operated upon on July 12, 1945—5 surface applications followed by 3 needle punctures over the site of the retinal hole, no muscle being detached. The retina went back and he was discharged from hospital on September 9, 1945, with a full field and the remarkably good central vision of $6/12$ and J. 2 with correction (fig. 2). On April 3, 1946,

FIG. 1.—Spr. J. A. A. Appearance of right fundus, July 5, 1945. An apparently total detachment of retina with small oval hole at 2.30 o'clock 6 mm. behind ora serrata.

FIG. 2.—Spr. J. A. A. Visual field to 1° white target September 9, 1945. Central vision with $\begin{smallmatrix} +4.0 \\ +1.5 \end{smallmatrix}$ \downarrow 165°
= $6/12$ and $+3.5$ added = J. 2.

visual acuity had improved to $6/9$ with aphakic correction $\left(\begin{smallmatrix} +4.25 \\ +1.25 \end{smallmatrix} \times 150^\circ \right)$ and with $+3.5$ added he read J. 1 with ease.

This case has been shown as an example of a remarkable restoration of central vision in an apparently total detachment of the retina. The wider question of the advisability of needling of both eyes in cases of congenital cataract is also raised. The incidence of a subsequent retinal detachment following discission of the lens is high. In a paper (1934), I stated that it was probably in the neighbourhood of 10%, and occurred after an average interval of twenty-five years; I suggested that one eye only be needled in childhood, its fellow being left in reserve unless the cataract were so dense as to make

The relative hardness of a number of cataract knives was found to be as follows:

Weiss A	760
Weiss B	780-810
Grieshaber	730-790

Apart from hardness, blades must possess a certain amount of toughness and this is usually determined by means of an empirical bend test. It is difficult to specify a suitable bend test as it depends so much upon the thickness and shape of the knife.

Beside carbon steels, stainless steel is also used for the production of fine-edged cutting implements. As its name indicates, it possesses the very desirable property of a degree of stainlessness. No steel is, however, absolutely stainless and the term is relative. In spite of possessing a very considerable degree of stainlessness, stainless steel has, however, the disadvantage of requiring a high heat-treatment temperature (approx. 1050° C.), of being insufficiently hard after heat-treatment, and of responding with difficulty to the operations of grinding, honing and stropping. Stainless steel for the manufacture of acute-angled cutting edges should contain not less than 14% chromium and 0.9% carbon.

From time to time cutting instruments have been made from special bronzes, but it is considered that none of them has been sufficiently hard to ensure durability.

Means for measuring sharpness and for determining the exact contour of a sharp cutting edge are available and in constant use.

By the use of specially constructed optical goniometers and of the diamond wedge interference method developed by one of the authors (J. F. K.), the angles of inclination of the minute facets that make up the extreme edge can be measured and the radius of curvature of the edge itself can be determined.

Instruments incorporating light-sensitive cells enable the detection of imperfections that are not visible under the microscope. With a specially adapted profilometer, the depths of grinding marks and of minute scratches on highly polished surfaces can be measured, although the surface itself may be less than 0.001 in. wide. A suitable profilometer is capable of measuring scratches that are not more than 0.000001 in. deep.

It is impossible to produce sharp edges uniformly without means for examining them during production and for that purpose a microscope fitted with a suitable illuminator is absolutely essential.

A standard microscope is quite suitable, but special attention must be paid to the illuminating system. The ordinary vertical illuminator such as is used on metallurgical microscopes is not satisfactory because it may give erroneous results. In this method of illumination a beam of light directed on to the specimen by means of a prism or "cover slip" reflector is reflected back from the specimen into the objective. Unless the surface is flat and at right angles to the optical axis of the microscope, the incident light will be reflected away from the microscope altogether. Since all cutting edges are bevelled, a different system of illumination must therefore be used and experience has shown that the most suitable procedure is to use a dark field illuminator.

The necessity for correct illumination is shown by figs. 2 and 3 which show the point of a keratome photographed at 100 magnifications. Fig. 2 was taken using dark field illumination from a Leitz Ultrapak, whilst fig. 3 shows the same area photographed with an ordinary vertical illuminator. In the second photograph the bevel cannot be seen and an entirely false impression is given of the edge.

Perfect edges are most readily produced by automatic machinery. Some knives, especially ophthalmic knives, unfortunately, do not lend themselves to automatic production. There are several reasons for this. In the first place the knives are very small and are only required in small quantities. Furthermore, the presence of a fixed handle seriously mitigates against automatic production.

All detachable knives should be made by automatic machinery but, unfortunately, some surgeons have a partiality for shapes that cannot properly be automatically produced. The result is that such knives never have a satisfactory cutting edge and, in spite of the fact that the surgeon may be happy with the shape of the blade, it is difficult to see how he can be equally happy with its sharpness. It is suggested that the surgeons should agree amongst themselves what shapes are necessary and, having agreed upon a reasonable number of shapes, should then insist on such knives being properly manufactured. In general, it may be said that straight edges are the most easily manufactured. By the provision of special cams certain types of convex-edged knives can be produced automatically, but there does not appear to be machinery capable of producing knives with concave edges.

As a result of extensive investigations carried out over a number of years, it has been established that the sharpest cutting edges (which unfortunately are only found with any degree of uniformity amongst safety razor blades) are made up of two minute mirror-like facets subtending an angle of 20 degrees to 24 degrees to one another. The radius of

Cutler of Sheffield the best method of testing the sharpness of a knife, and was referred to Mr. J. F. Kayser, the Senior Technician of Gillette Industries Limited.

Mr. Kayser, who is an Associate in Metallurgy of the University of Sheffield, is, I have since learnt, the leading international authority on cutting edges of all kinds, from those used in cutting steel to those used in trimming carpets. He has done much work on the cataract knife problem during the last five years.

PART I (J. F. K.)

A number of factors are involved in the production of sharp, acute-edged cutting implements, and they may be classified as metallurgical or mechanical factors. Metallurgical factors comprise, *inter alia*, choice of material, heat treatment and chemical and physical properties of the heat-treated knife, whilst shape, dimensions of edge, surface finish of facets, &c., are mechanical factors.

Safety razor blades and many surgical knives are made from cold rolled carbon steel containing approximately 1.3% carbon. Cold rolled material containing less than 1.3% carbon may, however, be used and for some purposes it might be preferable to use steel containing not more than 0.7% carbon.

As received from the steel maker, cold rolled steel has a bright, mirror-like surface and every endeavour should be made to preserve this surface throughout the heat-treatment process, and the material should leave the heat-treatment furnace as bright as it entered it. This can be easily achieved if heating takes place in an atmosphere of dry hydrogen or cracked ammonia. Fig. 1 shows two safety razor blade strips; one before heat-treatment and the other after heat-treatment. It will be noted that both look alike.

FIG. 1.

In general, the heat-treatment of a safety razor blade or surgical knife comprises two steps, hardening and tempering. Hardening consists in heating to a temperature somewhat above $750^{\circ}\text{C}.$, the exact temperature depending upon the composition of the steel, and cooling rapidly. Many knives can be heat-treated in strip form and if the cross section is not greater than 0.02 in. it is not necessary to quench in water or oil but one may quench by passing the flat strip between water-cooled blocks. Blades that cannot be hardened between water-cooled blocks must be quenched in oil. Many ophthalmic instruments fall in this latter class.

As originally quenched, carbon steel is too brittle for most purposes and it consequently must be tempered. Tempering consists in heating to a comparatively low temperature ($200\text{--}400^{\circ}\text{C}.$), the exact temperature and duration at the temperature depending upon the type of steel and the physical properties required. This temperature must again be controlled with very nearly the same accuracy as the hardening temperature.

Control of hardening and tempering temperatures is alone not sufficient to ensure a correctly hardened blade, and the product must be sampled and tested for hardness and toughness to ensure that heat-treatment has been satisfactorily carried out.

In the case of very expensive knives heat-treated individually, it is often desirable to measure the hardness of each knife and to submit a small percentage to a toughness test. In the case of blades that may be hardened continuously such as Bard-Parker knives, it is usually sufficient to determine the hardness approximately every 2,000 blades.

There are many different types of hardness tester, adequate descriptions of which are to be found in the technical literature. For such implements as surgical knives, the most useful is the diamond indentation test. In this test a diamond pyramid is pressed into the article to be tested under a constant load, and the hardness number is the quotient of the load in kilograms divided by the superficial area of the impression in square millimetres.

In the hardened state, before tempering, the hardness of acute-angled knives should be not less than 850 and may be as high as 900 to 925. In general, such high hardness goes hand in hand with brittleness and the steel should be tempered to reduce the hardness to approximately 800.

The relative hardness of a number of cataract knives was found to be as follows:

Weiss A	760
Weiss B	780-810
Grieshaber	730-790

Apart from hardness, blades must possess a certain amount of toughness and this is usually determined by means of an empirical bend test. It is difficult to specify a suitable bend test as it depends so much upon the thickness and shape of the knife.

Beside carbon steels, stainless steel is also used for the production of fine-edged cutting implements. As its name indicates, it possesses the very desirable property of a degree of stainlessness. No steel is, however, absolutely stainless and the term is relative. In spite of possessing a very considerable degree of stainlessness, stainless steel has, however, the disadvantage of requiring a high heat-treatment temperature (approx. 1050° C.), of being insufficiently hard after heat-treatment, and of responding with difficulty to the operations of grinding, honing and stropping. Stainless steel for the manufacture of acute-angled cutting edges should contain not less than 14% chromium and 0.9% carbon.

From time to time cutting instruments have been made from special bronzes, but it is considered that none of them has been sufficiently hard to ensure durability.

Means for measuring sharpness and for determining the exact contour of a sharp cutting edge are available and in constant use.

By the use of specially constructed optical goniometers and of the diamond wedge interference method developed by one of the authors (J. F. K.), the angles of inclination of the minute facets that make up the extreme edge can be measured and the radius of curvature of the edge itself can be determined.

Instruments incorporating light-sensitive cells enable the detection of imperfections that are not visible under the microscope. With a specially adapted profilometer, the depths of grinding marks and of minute scratches on highly polished surfaces can be measured, although the surface itself may be less than 0.001 in. wide. A suitable profilometer is capable of measuring scratches that are not more than 0.000001 in. deep.

It is impossible to produce sharp edges uniformly without means for examining them during production and for that purpose a microscope fitted with a suitable illuminator is absolutely essential.

A standard microscope is quite suitable, but special attention must be paid to the illuminating system. The ordinary vertical illuminator such as is used on metallurgical microscopes is not satisfactory because it may give erroneous results. In this method of illumination a beam of light directed on to the specimen by means of a prism or "cover slip" reflector is reflected back from the specimen into the objective. Unless the surface is flat and at right angles to the optical axis of the microscope, the incident light will be reflected away from the microscope altogether. Since all cutting edges are bevelled, a different system of illumination must therefore be used and experience has shown that the most suitable procedure is to use a dark field illuminator.

The necessity for correct illumination is shown by figs. 2 and 3 which show the point of a keratome photographed at 100 magnifications. Fig. 2 was taken using dark field illumination from a Leitz Ultrapak, whilst fig. 3 shows the same area photographed with an ordinary vertical illuminator. In the second photograph the bevel cannot be seen and an entirely false impression is given of the edge.

Perfect edges are most readily produced by automatic machinery. Some knives, especially ophthalmic knives, unfortunately, do not lend themselves to automatic production. There are several reasons for this. In the first place the knives are very small and are only required in small quantities. Furthermore, the presence of a fixed handle seriously mitigates against automatic production.

All detachable knives should be made by automatic machinery but, unfortunately, some surgeons have a partiality for shapes that cannot properly be automatically produced. The result is that such knives never have a satisfactory cutting edge and, in spite of the fact that the surgeon may be happy with the shape of the blade, it is difficult to see how he can be equally happy with its sharpness. It is suggested that the surgeons should agree amongst themselves what shapes are necessary and, having agreed upon a reasonable number of shapes, should then insist on such knives being properly manufactured. In general, it may be said that straight edges are the most easily manufactured. By the provision of special cams certain types of convex-edged knives can be produced automatically, but there does not appear to be machinery capable of producing knives with concave edges.

As a result of extensive investigations carried out over a number of years, it has been established that the sharpest cutting edges (which unfortunately are only found with any degree of uniformity amongst safety razor blades) are made up of two minute mirror-like facets subtending an angle of 20 degrees to 24 degrees to one another. The radius of

curvature of the extreme edge is approximately 0.00001 in. A good edge is never saw-like but is essentially straight even when examined at magnifications as high as 500 times.

A photomicrograph of a sharp cutting edge such as may be found on many safety razor blades and some surgeons' knives made under optical control by modern mass production methods is shown in fig. 4.

FIG. 2. $\times 100$.

FIG. 3. $\times 100$.

FIG. 4. $\times 50$.

FIG. 5. $\times 50$.

FIG. 6. $\times 50$.

FIG. 7. $\times 50$.

The final facet (the facet adjacent to the edge) is, for all practical purposes, free from scratches, and the few present are less than 0.00001 in. deep.

The final facets of most surgeons' knives appear only to be rough ground, and the scratch depth frequently exceeds 0.0001 in., with the result that the edges are saw-like. Fig. 5 shows the edge of a detachable knife taken from a packet of knives, no two of which were alike and which appeared to have been made without any control.

Figs. 6 and 7 show the points of two knives (both made by the same manufacturer). These were carefully removed from the package by one of the authors (J. F. K.) and the photographs show the blades as they would be received by the operating surgeon. It should be particularly noticed that figs. 4, 5, 6 and 7 were not taken at particularly high magnifications, but only at 50 diameters.

As might be anticipated from their minuteness, sharp cutting edges are extremely fragile and if they are to be packed without damage it is necessary to exercise a considerable amount of thought and skill.

It is indeed highly probable that they undergo more damage when being packaged and at the hands of the theatre nurse responsible for taking them out of the package and sterilizing them than is incurred during normal use.

There are two aspects to the damaging of sharp-edged instruments, namely the mechanical and the chemical side. A slight touch will severely damage an edge and there is a very marked difference in the way in which a really sharp knife and one damaged by careless handling will cut tissue.

Carbon steel cutting edges are particularly prone to corrosion and should always be adequately protected by the manufacturer, but the manufacturer cannot be held responsible for corrosion that may occur when the knives have been removed from the original package.

Particular care must be taken not to damage sharp-edged knives during sterilization. Sterilization of detachable blades at 160°C . for ten minutes is quite permissible as such blades should never be used more than once; repeated sterilization at 160°C . or over will soften the steel.

It must not be forgotten that many sterilizing solutions attack steel.

In general, all solutions having a pH value lower than 7, i.e. possessing some degree of acidity, have a corrosive action on steel. On the other hand, many solutions having a pH value above 7, i.e. possessing some degree of alkalinity, are non-corrosive to steel at room temperatures; at temperatures near to 100°C ., however, some corrosion of the cutting edge may take place and the slightest corrosion is sufficient to blunt a sharp cutting edge.

It is not always possible to predict corrosive tendencies from the presence or absence of a particular element in the sterilizing solution because much depends upon the manner in which the element is combined. For example, free chlorine or iodine, or tincture of iodine, are strongly corrosive to steel, and so also is alkaline hypochlorite. On the other hand, alkaline preparations of chloro-xyleneols are non-corrosive. A potentially corrosive effect may often be prevented by the presence of an alkaline ingredient. Lysol in alcohol (1 : 2) and liquor chloro-xyleneolis B.P. both contain soap, whilst liquor boracis et formaldehydi contains borax; all three solutions may be safely used.

FIG. 8.

Care must be taken not to allow instruments to stand in solutions that have a tendency to crystallize out. If that happens small crystals always concentrate on the cutting edge as shown in fig. 8.

Pure alcohol has no corrosive effect on steel but alcohol in contact with air invariably contains traces of oxidation products, i.e. aldehyde and acetic acid, and it then has a tendency to promote corrosion.

curvature of the extreme edge is approximately 0.00001 in. A good edge is never saw-like but is essentially straight even when examined at magnifications as high as 500 times.

A photomicrograph of a sharp cutting edge such as may be found on many safety razor blades and some surgeons' knives made under optical control by modern mass production methods is shown in fig. 4.

FIG. 5. $\times 50$.

FIG. 6. $\times 50$.

FIG. 7. $\times 50$.

The final facet (the facet adjacent to the edge) is, for all practical purposes, free from scratches, and the few present are less than 0.00001 in. deep.

The final facets of most surgeons' knives appear only to be rough ground, and the scratch depth frequently exceeds 0.0001 in., with the result that the edges are saw-like. Fig. 5 shows the edge of a detachable knife taken from a packet of knives, no two of which were alike and which appeared to have been made without any control.

The Manchester Eye Infirmary is the largest in the country, and has a large stock of new and once used eye instruments ready for use. By permission of Mr. Duthie 122 of these, including cataract knives, needles, keratomes, and trephines, were examined optically (average time per unit 64 sec.).

Group A (unused)

Rejects 11.9% { 2.5% Rust alone
9.3% Constructional defect

Group B (used but still regarded as usable)

Rejects 47% { 11.4% Constructional defect
18.0% Rust alone
17.6% Defect + rust

Are operations easier on the whole with optically selected instruments? After four years of the method my answer is emphatically: Yes.

Can manufacturing methods be improved by optical control? The adoption of a standard (detachable) handle and a uniform size and shape of blade would permit mass production of a knife based on the V. Graefe "Schmalmesser", under optical control with a Gillette edge and a perfect point.

Such a machine is only financially practical if an output of at least 2,000 blades a day could be absorbed.

Hand production requires half an hour's exact and laborious grinding per blade, the final edge being produced by setting up on a hone. The output is limited by the small number of men who can do the work (Downs).

Knives produced experimentally in beryllium bronze and stainless steel were inferior optically and clinically to the usual material (Huntsman's 0.8% carbon yellow label). Points back-sharpened for 2 mm. proved liable to bend.

Trephines.—Experiments are still proceeding to improve the edge by touching with a stone while rotating in an air motor at 20,000 r.p.m. and altering the tempering process to eliminate pits and cracks, though the obturator in a rust-narrowed bore may cause some of the latter.

In conclusion our thanks are due to the Directors of Gillette Industries Limited, Down Brothers Limited, and C. F. Thackray Limited of Leeds, for their help in carrying out this investigation. As lack of space has limited us to a précis of the paper, and a fraction of the large photographic material, it is hoped to republish this paper in *extenso* in the *British Journal of Ophthalmology*.

The Chairman said the authors had opened up all sorts of ideas as to the best way of tackling this problem. He would like to see something in the nature of an N.P.L. certificate issued.

Mr. R. Lindsay-Rea remarked on what he considered to be the value of sharpening the point on the back of the cataract knife. He would not like to use a knife sharpened on the back so much as 2 mm. The first cataract knife he tried was not sharpened on the back. Then it occurred to him that any knife sharpened both back and front must go through best, so he had the back of the knife sharpened 1 mm. He believed it was Mr. A. McCurry who drew his attention to the benefit of that at the time. For a good many years he used that knife, which was manufactured by two firms. In the middle of the war, he supposed, there were difficulties and, for the first time, the point of a cataract knife bent back on him as he was trying to emerge from the anterior chamber. He did not want to withdraw the knife and he could not push it through, so he patiently scratched his way out. He kept the knife carefully and afterwards returned it to the maker, who apologized for a piece of bad tempering. That was the only one out of a great many dozen he had used with which he had had such an accident.

Whatever instrument was devised—a cataract knife had to be good if one was going to get a reliable edge. If one had a good knife it should cut easily through a cornea but one still must saw. He had seen a man take a knife and with one stroke cut through as if cutting through a piece of cheese. It was very severe on the eye, a bad incision; the cut through the cornea did not come back into the sclera. He could not understand his colleagues wanting a whippy knife. The finer the instrument the better, provided it was strong and reliable. His own knife had a strong back and could be trusted; it was possible to cut through without losing aqueous. A number of his knives had found their way across to the United States and there they were being used freely. Some workers had realized that a knife half the size of the Graefe was very effective and a good cataract knife, but it must be well made. The Graefe was too large.

Mr. J. Foster said that he agreed with Mr. Lindsay-Rea that a whippy knife was not good. He had never been able to understand why any surgeon should want a knife of this type, but had been told by the Weiss experts that some surgeons preferred them this way. If any surgeon in the meeting had this preference he would be interested to know the reason for it.

He would like to make clear that the trial drum had never been really adequate for testing trephines or keratomes, and that keratome points were amongst the most defective he examined. As he had explained previously, these instruments were the most difficult of all to make. In addition to this, there were many instruments which would pass the trial drum, but which would not pass the microscope. He had never seen the converse occur.

Stainless steel instruments, as their name implies, are much more resistant to corrosion than carbon steel instruments, but the halogens, e.g. chlorine and iodine, attack them so that even when using stainless steel knives, care must be taken when choosing a sterilizing medium.

PART II (J. F.)

Kayser's methods applied to new and unused cataract knives reveal that a new knife for every operation is no solution of the problem, as about 6 to 10% are defective from rust, have blunt, chisel-like, or oversharpe points, and the edge build-up is inconsistent, sometimes poor, and always inferior to a Gillette blade.

Technique.—To obtain a safe mobility on the moving stage, special holders had to be designed. That illustrated (fig. A) holds cataract knives, needles and straight keratomes, with the ground zone roughly horizontal. Keratomes require a small stand and trephines a device allowing rotation (photographs not reproduced).

Pass standards (knives).—Schmidt's "Einzügige Starschnitt", Terrien's "Mouvements d'Archer", and biopsy of operated cadaveric eyes (St. James's Hospital, Leeds) suggest a

FIG. A.—Cataract knife holder. Lateral notches can be varied to different stage arm fittings.

FIG. B.—"Unstable" point. Liable to fracture and remain in the anterior chamber. $\times 240$.

FIG. C.—A good cataract knife edge. Compare the slight irregularity of the edge and the grinding marks with the Gillette blade. $\times 88$.

wedge-cutting action, that a fine point and straight edge are optimal, and that instruments should be used once only.

Surgeons who prefer to "saw", a shortage demanding repeated use, and the limitations of hand grinding, force a compromise on these points.

Exclusion of laterally bent, obviously blunt, and unstable points (fig. B) out of batch of new knives, will leave the rest to provide a rough standard.

A perfect point was shown for comparison (not reproduced) and a photograph of a good edge is seen in fig. C. A slight irregularity is observable. Notches even though < 0.02 mm. wide should reject unless near the heel. Slight rust on the flat can be passed, but not on the ground zone. The best knives have a ground zone 0.03 to 0.07 mm. wide on which the grinding marks are just visible. Ziegler knives have an edge comparable with this when new, and poorer after regrinding. Keratome edges are always inferior to it.

The many British and few Swiss knives examined were superior to most American. Such French and German knives as could be obtained were of a lower standard.

Trephines.—These are softer (VDH 473), and more prone to rust and structural defects (50% in some types) than cataract knives. The problem is which defects can be passed at a time of scarcity. "Chips" out of the ground zone, small notches (unless enlarged by rust) and splits unless curled in or "veed out" can be tolerated though they slow up cutting. In times of plenty such instruments should be rejected and resharpened unless a pitted or perforated barrel indicates future defects. Magnification $\times 40$ is adequate, and the wide objective permits a view of the interior of the barrel.

Are there enough defective instruments in circulation to justify optical control?

The Conduct of a Case Wishing to be Fitted with Contact Lenses

Discussion.—Many patients have quite erroneous ideas as to what can be achieved with contact lenses. After the usual data have been recorded and a short ophthalmic history taken, the purpose for which the lenses are required should be considered. Improved vision not obtainable with spectacles, certain well recognized conditions, such as keratoconus and mustard-gas burns of the cornea, are undoubted indications but most cases do not fall into this therapeutic group. The majority of patients can see well with spectacles but for one reason or another wish to discard them. In that case it is wise to ask: "What do you hope to achieve with contact lenses that you cannot do either with or without your spectacles?" Ball games, swimming, some trade or professional difficulty or disability that can be overcome, are good answers and suggest that the patient is likely to have sufficient drive to master the discipline of contact lens wearing and to use them regularly. It is surprising how many trade and professional difficulties exist which are a great handicap to the patient and which can be removed by contact lenses. Each case should be judged on its merits and candid advice given.

Next the patient should be warned that on the average contact lenses are worn not more than four hours continuously with comfort and efficiency, and it should be pointed out that while he may hope to wear them for more than one such period in one day on occasion he will not be able to do so as a rule. There is a personal limit, varying from case to case, to the hours of continuous wear, the hours of wear on any one day, and the number of hours the lenses can be worn in a week. Four hours a day and twenty-eight hours a week is the average of all cases, both good and bad, in this series. About 20% of cases fall out at this stage.

Fitting of Dixey Lenses

A full routine ophthalmic examination is done. If anything is observed which might make the wearing of contact lenses unwise, such as degenerative changes in the region of the ora serrata, previous needling for congenital cataracts, or any active inflammatory disease, contact lenses should be ordered only after these objections have been carefully assessed for the particular case.

An accurate refraction is now done, the corneal diameters measured with callipers and the patient's corneal radii measured with the keratometer. This use of the keratometer involves complete suppression of the observer's accommodation as is the case in measuring swelling of the optic disc. Absolute readings are required, not the difference which records only the corneal astigmatism. The author uses an Ellis instrument which is robust, very accurate and easily calibrated against a steel ball of known radius.

We may now select from the trial set of afocal lenses a lens of suitable corneal radius and diameter. The scleral radius is estimated by inspection. The lenses in the trial set are all decentred except those in white boxes, and the amount of corneal decentration on each trial lens is the result of experience. It may be altered at will by the prescriber.

Having selected a trial lens it is filled with a solution of fluorescein (1/500 is a suitable strength and is made up in the contact lens solution it is proposed to use).

The lens is now inserted placing the narrow nasal scleral edge towards the patient's nose. The author does not use any anæsthetic drops except in very nervous patients, and it is doubtful if such patients are likely to be successful wearers. If the patient is engaged in conversation and the rationale of each step explained it is unusual to meet any real difficulty. Nevertheless it should be observed that this is the stage at which unpleasant difficulties do arise. If the patient is temperamentally unsuitable, or if his eyes are mixed up in his mind with some psychoneurotic disturbance, he may react violently. This series includes two hysterical fits and one severe fainting attack. Apart from these severe reactions many patients react badly at this stage, becoming pale and sweating profusely. All the severe reactions and most of the less severe ones, have occurred in men. The author does not proceed with such cases, unless the wearing of contact lenses is of real therapeutic importance.

After the lens is inserted it is inspected directly for fit and then examined under a powerful cobalt blue light. This is best obtained by using an ophthalmic operating lamp fitted with a cobalt blue glass filter of suitable density. Plenty of blue light is necessary. Under this illumination the fluorescein fluoresces brilliantly and the very thin film under the lens, wherever it is not actually touching, becomes apparent. This technique of fitting is attributed to O'brig; it is an important advance. While it is best to work with the patient's face turned away from the light, darkness is both unnecessary and undesirable. From this point fitting proceeds by a process of trial and error and is largely a matter of practical experience. It is not proposed to give any detailed instruction but the following diagrams may assist towards an appreciation of the theory underlying contact lens fitting.

[June 27, 1946]

Recent Developments in the Manufacture, Fitting and Prescription of Contact Lenses of Regular Shape

By, FREDERICK RIDLEY, F.R.C.S.

THE firm of Zeiss produced spherical contact lenses by grinding in 1892. In 1929 Professor Heine introduced what may be called "the afocal lens approach" and a series of lenses of this type were offered by Zeiss. The range of fittings increased as experience was gained and latterly the full set comprised a range of some 700 lenses.

Even so the necessary range of fittings to accommodate the varying corneal diameter was not provided. It was against this background that Dallos introduced his glass, moulded contact lenses in 1933. These lenses have a scleral segment of irregular contour corresponding precisely to the patient's sclera. This correspondence was at first secured by making the lens to a mould from each eye but latterly has been obtained by adapting by hand a ready-made lens of approximately the correct shape. At one sweep most of the difficulties were removed and a practical contact lens, adaptable to almost any patient that could possibly wear one, became available. The success of the method was so great that the increased cost, the tedious and prolonged fittings by a technician and the troublesome taking of a mould from each eye were accepted and, for the time being, further consideration of the improvements possible along the lines initiated by Zeiss was abandoned.

The introduction of glass-like plastics especially those based upon methyl methacrylate offered a suitable material for contact lenses about 1937 and Obrigg in America succeeded in making a moulded irregular contact lens from this material in 1938. The advantages of this organic plastic are that it is only 40% as heavy as glass and moreover can be used as thin as 0.3 mm. without difficulty; it is unaffected by tears; it is flexible without undergoing permanent distortion and is almost unbreakable; it has a low thermal conductivity so that it feels warm; it has a quality of soft resilience and smoothness when wetted by tears which makes it almost imperceptible to the lids. As developed by I.C.I. in this country, methyl methacrylate, called "Transpex 1", is available with a guaranteed refractive index of extreme precision and its optical qualities are equal and even superior in some respects, to the finest optical glass; it is free from strain and is perfectly homogeneous.

Messrs. Dixey of London attacked the problem of contact lens production from an entirely new angle. They evolved a lathe of such precision that a lens may be turned from the solid block of Transpex. These lenses are not afocal but calculated upon a known base curve for the back surface of the cornea, 7.0, 7.5; 8.0 or 8.5 mm. radius being employed. Experience quickly presented the same difficulties that had formerly confronted Zeiss, but in their new lathe Messrs. Dixey had an instrument of such flexibility that lenses of any corneal or overall diameter: lenses decentred to any amount; lenses made oval to any extent and decentred to any required amount along any axis in relation to the long axis of the oval, were soon produced. The production of a lens correcting astigmatism in both the corneal and scleral portions is also possible.

With such regular lenses consisting of two intersecting curves about three-quarters of the cases suitable for contact lenses can be adequately fitted, the remainder need irregular lenses. The advantages of regular over irregular lenses are ease and quickness of fitting; the fact that a trial of several hours wearing of a lens almost identical with the one it is proposed to order can be made as a routine; the fact that the ordering of a contact lens can be reduced to a prescription similar in form to a spectacle prescription; speed of fabrication (under normal conditions it should be possible to supply a pair of lenses in less than a week), and relatively small total cost. The patient needs to devote normally only one half-day to the fitting and the prescription is handed to him by the oculist as is the case with spectacles. When the lenses are ready he is taught to use them.

The numbers on the drawings define the measurements of lenses and eyes, they will not interest the general reader. The figures for a lens are arranged as follows and are always in millimetres. Scleral radius/ Corneal radius of back surface of lens/ Corneal diameter/ Overall dimensions of lens/ Decentration of corneal part of lens/ The spherical modification of the afocal trial lens used which is needed to give optimum vision/ Vertex distance from front surface of contact lens to centre of principal lens in the trial frame. The last two figures will normally appear only in a prescription. To facilitate inscribing and as a convention, the initial digit and the decimal point may be dropped, thus—12.5 may read 25. The drawings give a true impression of the relationships rather than a diagrammatic one.

FIGS. 1 and 2.—These figures, taken from Oberg, show the amount of play at the limbus that is desirable in a contact lens. It may be said that no contact lens can be comfortably worn if it presses upon the cornea continuously at any point. Ideally the lens should float symmetrically about the cornea on a tears film which separates it from the sclera, and this relationship should be maintained in all directions of gaze. To meet this requirement when looking nasally as in reading, lenses should usually be decentred.

FIG. 3.—This drawing of two similar circles intersecting demonstrates first, the form of an afocal lens—the shaded area. The surfaces are of similar radius, and are not concentric. Regarded as a lens fitting a globe it is seen that the separation of the two surfaces is greatest at the apex and diminishes to nil in the equatorial region. The width of a 20 mm. lens on a 12 mm. radius scleral circle is drawn to scale and it is seen that the separation at the lens edge is less than one-half of that at the apex. This is important in fitting. A lens of slightly less radius than the eye to be fitted will be supported by a capillary film of tears over a wide area towards the periphery while standing away from the eye centrally. This diminishing separation towards the periphery gives a delicate natural adjustment which the fitter uses to secure his result.

FIG. 4.—Demonstrates the importance of corneal diameter in relation to corneal radius. As the corneal diameter increases the periphery of the corneal segment falls back towards the centre of the eye. Thus, for the same eye, as the corneal diameter of the contact lens is increased the corneal radius may also be increased considerably without touching the cornea. As a corollary we may increase the corneal diameter of the trial lens using the same corneal radius without risk of producing a lens that will touch the cornea. To diminish the corneal diameter without diminishing the corneal radius is to court trouble.

Figs. 5 to 14 are scale drawings to demonstrate the appearance seen when fitting, using fluorescein and blue light, alongside the section of the eye and contact lens.

FIG. 5.—Perfect fitting. Note that a contact lens of corneal radius 8.0 clears a cornea of 7.8 mm. radius if the corneal diameter is 0.5 mm. greater than the actual corneal diameter. This gives the necessary play or lag, see figs. 1 and 2.

FIG. 6.—Too tight, the lens stands away from the eye and rests on its edge where the conjunctival vessels will be compressed and a white area will be seen. The fluorescein fills the lens. Note how much the lens stands away for an error of only 0.5 mm. scleral radius in fitting.

FIG. 7.—Too loose. The lens bears upon the ciliary region and only just clears the cornea. The fluorescein fills the lens at first but is quickly washed away by the tears so that the appearance drawn is more characteristic.

FIG. 10.—If a drop of 1% fluorescein is used the gapping area will be filled. If the lens is gapping only at certain points, as often happens especially above, the fluorescein will run in as drawn.

FIG. 8.—The contact lens touches the cornea. The fluorescein appearance is of a black central area.

FIG. 12.—These drawings illustrate the two simplest ways in which corneal astigmatism may be accommodated to the sclera. The refraction shows 3 D horizontally which corresponds to corneal radii of 8.0 horiz. and 7.5 vertically approx. Both curves must pass through the same apex. In all three curves the same ideally fitting contact lens is superimposed on the eye. The middle diagram shows the perfect fit in the horizontal meridian. The lower diagram (vertical section) shows the shorter corneal radius carried only as far as the projected scleral curve. Such a cornea would be narrowed in the vertical meridian but the contact lens would fit perfectly. The upper diagram shows the corneal curve carried on to meet the scleral curve at the same corneal diameter (12 mm.) as in the horizontal plane (centre diagram). In this case the contact lens stands away from the eye at the limbus and such a case would probably need a moulded lens.

It may be supposed, however, that the scleral curve in this meridian has to reach the same equatorial diameter as in the horizontal meridian. This means that the scleral radius must be greater in the vertical direction than in the horizontal and the further the contact lens is carried towards the equator the closer it will approximate to coincidence with the sclera. An oval lens with the long axis vertical may fit the eye satisfactorily.

FIG. 9.—Shows, on the left, the wrong way to attempt to fit such a case. The scleral radius of the lens is too small and this produces a tight area horizontally without closing the gap above. The tight area is indicated by strokes and the gapping area, where bubbles will enter in use, is shown by small rings. Diagrams showing the extent of the fluorescein and the tight and loose areas should be made in every case.

The right-hand picture shows the same case fitted with an oval lens, 19 x 22, of the correct scleral radius. The lens now bridges the gapping area and comes into sufficiently close approximation with the sclera at its upper and lower edges to prevent bubbling.

FIG. 14.—Shows the effect of decentration upon the fit of a lens of slightly shorter scleral radius than the eye. It has the effect of flattening the fit of the narrower flange of the lens.

FIG. 13.—This shows the effect of decentration (drawn upwards for convenience of illustration) upon the fluorescein appearance. Note that the fluorescein pool is concentric with the contact lens flange but displaced in relation to the corneal segment.

FIG. 11.—To show, left hand, the appearance of a corneal crescent on looking nasally. The lens is pushed against the cornea. This is met by decentring the lens. The centre diagram shows 0.5 mm. decentration which is inadequate, and the right hand diagram 1.0 mm. decentration. This gets rid of the crescent but, as drawn, the lens now fits the sclera right up to the limbus, that is, it is too "flat". The effect on the temporal side is the opposite of that on the nasal side but is of less practical importance.

Acknowledgment is due to T. E. Oberg for the use of figures 1 and 2 from "Contact Lenses", 1942, New York, and to Dr. P. Hansell, Westminster Hospital Medical School, Department of Medical Photography, for the preparation of the film strip from which illustrations 3 to 14 are taken.

FREDERICK RIDLEY: Recent Developments in the Manufacture, Fitting and Prescription of Contact Lenses of Regular Shape.

Table III shows that after 20% of patients have been rejected at interview, 5% react badly to the fitting (sweating &c.) and 12%, despite a good fit, develop reddening or weeping sufficient to make the ordering of lenses inadvisable. 1% (or rather more) do not tolerate any solution. Of this 18% of "unsuitable" cases some abandon the fitting because, when they have tried the lens in, they decide they do not like the proceeding; no attempt has been made to dissuade such patients. Of the total 65% have been fitted with Dixey lenses and 17% were considered suitable for moulded lenses but not suitable for Dixey lenses.

TABLE III.—ANALYSIS OF 200 CONSECUTIVE CONTACT LENS CASES.
(Rejected as unsuitable at interview, 20%, 40 cases.)

Results (fitting)—160 cases	% of 160 cases
Dixey lenses ordered...	65 or 104 cases
Unsuitable personality	5 or 8 cases
Unsuitable physical reaction to lenses	12 or 19 cases
No solution tolerated	1 or 2 cases
Considered suitable for moulded lenses	17 or 27 cases

Table IV tabulates the answers to a questionnaire sent to all patients in the series resident in the British Isles, many are resident abroad and others were away on service overseas. The answers show that most of the patients are satisfied with their lenses and actually wear them an average of rather more than four hours every day—twenty-eight hours each week. This average includes all those wearing the lenses but excludes those who have given up their lenses for one reason or another (4 cases). 20% wear the lenses less than four hours and must be considered unsatisfactory. On the other hand, 28% wear them more than six hours daily—eight and a half, ten, twelve and thirteen hours daily average occur in the 29 replies received and this figure is perhaps unexpectedly good

TABLE IV.—RESULTS IN USE.

A questionnaire was sent to the 60 patients living in Britain and 20 replies received.

<i>Are you satisfied with your lenses?</i>			
Yes	20	70%	
No or qualified Yes	9	30%	
Cannot put them in or "lost interest"	4	9%	13%
Worn two hours or less	5	17%	30%
<i>How long can you wear them?</i>			
Average of 19 replies giving actual figures	5½ hours		
<i>How long do you wear them?</i>			
Daily average (20 replies) excluding 4 not wearing	Hours		
5	2	20%	
8	4	30%	
5	4-6	20%	
7	Over 6	28%	
Average of exact times given	4½ hours.		
<i>Weekly average</i>			
Average of exact times given	28 hours.		

Apart from the questionnaire the records contain 49 reports of times worn—by patients or friends reporting about them. The average is again five hours, which suggests that the above detailed analysis may be reasonably regarded as a fair sample of the whole series.

CONCLUSION

This review of the case history of 200 consecutive patients who sought to wear contact lenses is perhaps the first of its kind. Similar analyses of larger numbers by different workers will be needed before any definite conclusions as to the efficacy of contact lenses as a whole, or of any particular type, can be arrived at. It is believed that this series justifies a revival of interest in the spherical or regular type of lens. The series suggests that some 80% of cases suitable for contact lenses can be fitted by the Dixey pattern lens leaving not more than 20% needing the irregular type, usually made to correspond to a mould taken from the eye. Probably all cases should be tried with the Dixey pattern lens in the first instance in order to eliminate those who prove unsuitable for personal or physical reasons.

An important aspect of this problem is the fact that Dixey lenses are ordered on a prescription similar to that normally employed for spectacles. In suitable cases the surgeon can conduct the whole examination and fitting in half a day in his consulting room, arriving at a clear formula to which the lenses can be made with great accuracy and in a short time. By this means a patient can visit any surgeon with the necessary training and obtain his prescription in a few hours. Unsuitable cases are eliminated quickly and with the minimum of trouble and expense to the patient. Moreover the decision as to whether a patient is suitable or not rests, as it is submitted it should do, with the surgeon. Many factors have to be assessed which belong properly to the sphere of the oculist and not to that of the technician. The fitting itself demands accuracy of

The fitting completed, the refraction is done again to determine the modification necessary. There is a tendency to accommodate strongly for some time after the lenses are fitted and this must be looked for. The following rules are of general application.

(1) The additional lens will be very near indeed to the addition predicted by the Zeiss charts if the first refraction, the keratometer readings and the fit are correct. A discrepancy of more than 8.0.5 should excite suspicion that something is wrong.

(2) The two eyes will show almost exactly the same deviation from the predicted values and in the same sense unless there is considerable anisometropia.

(3) The refraction with the lens in should be done with cylinders exactly as is the practice for spectacles. Some lenticular astigmatism is commonly found and the spherical modification of the lens ordered should be the sphere of the full correction excluding the cylinder. If this is not done, either axis of the total refraction may be corrected, perhaps in the opposite sense in the two eyes. This produces accommodative imbalance and difficulty with contact lenses just as it does in wearing spectacles. Some visual acuity must be sacrificed but the cyl. involved rarely exceeds 0.75.

Typical Prescription

	Ref'n: S. -2.75/-0.75 @ 120°	6/5		Ref'n: S. -3.50/-0.5 @ 60°	6/5
R.E.	C.L.: 25/8/13/20 x 22		L.E.	C.L.: 22/5/8/13/20 x 22	
	dec. 0.5 mm. L.A. (long axis)			dec. 0.5 mm. L.A.	
	Add minus 8.3.5			Add minus 8.4.25	
	at 9 mm. V.D.	6/5		at 9 mm. V.D.	6/5

It has been observed repeatedly in eyes showing no astigmatism by retinoscopy or subjectively, that the keratometer shows up to 0.75 of corneal astigmatism compensated by the same amount of lenticular astigmatism, as shown by the final refraction with contact lens in. The mechanism of this is not clear. It would appear that corneal astigmatism may be compensated to a limited degree by an opposite lenticular astigmatism possibly due to unequal ciliary contraction. The alternative would be that the cornea or the lens grows so as to produce a compensating astigmatism.

TABLE I.—PERCENTAGE ANALYSIS OF 200 CONSECUTIVE CONTACT LENS CASES.

200 cases			
Sex:	Males	63
	Females...	...	37
Age:	20 and under	8
	20-30	65
	30-40	20
	40-50	7
Purpose:	Sports	35
	Trade and profession	29
	Social	32
	Special	4
Refraction:	Over plus 5	1
	0-plus 5	6
	0-minus 5	60
	- 5 to -10	18
	-10 to -15	15
	-15 to -20	0
	Astigmatism of 2 to 3 D	4
	over 3 D	3
Result of interview—	Considered suitable for C.L.	80
	Considered unsuitable	20

Table I shows a big preponderance of males, perhaps due to the large number of Service men seeking lenses in the latter part of the war period. The 20 to 30 age-group is much the largest. The cases are evenly distributed between those seeking lenses for sports, trade and professional, and social reasons. Myopes of low degree dominate the picture.

TABLE II.—ANALYSIS OF 200 CONSECUTIVE CONTACT LENS CASES.

Contact Lens Measurements ordered	% second 100*	
Scleral radius:	11.5 mm. or less ...	0
	11.75 and 12.0 ...	23
	12.25 ...	45
	12.75 ...	32
	13.0 ...	0
	over 13.0 ...	0
Corneal radius:	7.5 mm. ...	6
	8.0 ...	65
	8.5 ...	29
Corneal diameter:	12.0 mm. or less ...	0
	12.25 and 12.5 ...	12
	12.75 ...	33
	13.0 ...	43
	13.25 ...	12
	13.75 ...	0
	over 14.0 ...	0

* A wider range of trial lenses became available for the second hundred cases.

Table II shows the distribution of contact lens measurements. The majority of scleras have a radius of 12.5 mm. The corneal diameter is at least 13 mm. on the average.

Further detailed analysis shows that there is no correlation whatever between the scleral and corneal measurements. Thus in the whole series there are very few cases of "average" eyes (i.e. 12.5/8/13) while 11.5/8/14 and 13/7.5/12 actually occur. These findings suggest that these measurements are biologically independent of one another.

INDEX

refraction and a good deal of judgment which surgeons already possess by reason of their training and experience.

 OBRIG, T. E. (1942) Contact Lenses. New York.

Professor Ida Mann said that Mr. Ridley had given a most interesting account of a group of cases of which she had no real experience. Her own cases had not been comparable, in that she had omitted the cosmetic group and had dealt almost entirely with patients showing an absolute rather than a relative indication. She had found that the Zeiss type of lens gave often good results in conical cornea, but not usually in the other groups. She had had one or two interesting cases which had started with Zeiss lenses, but had been dissatisfied with the short length of wear—four hours—and had demanded a longer wear and this had been obtained with individually fitted lenses. She had encountered now and then an hysterical case, and her experience was that one should not despair even of hysterical people; she had urged them to go through with the individual fitting, and some of them had acquired complete tolerance. Many of her patients were unable to work without contact lenses and therefore required a minimum tolerance of eight hours a day. In one series of 84 such cases this had been attained in 39 of them with individually fitted lenses.

Mr. Purvis asked whether the new plastic material used was any harder than the material in current use for spectacle lenses.

The Chairman (Mr. Humphrey Neame) said that his experience as to the length of time such lenses could be worn had been that different cases varied considerably. He had mostly to deal with mustard-gas keratitis pensioners. The people concerned wanted to use their lenses for as long as possible so as to do a day's work. Some of them wanted to use them for twelve hours a day. He had not got all the figures but certain of these keratitis cases did not tolerate the lenses for more than three or four hours, while a good proportion of them were able to wear them for eight to twelve hours.

Mr. Ridley, in reply, pointed out that the minute "scratches" which occur on most plastic lenses after they have been in use for some time, are not true scratches but rather what are technically called "sleeks". The material is not fractured at the edge of the mark but there is a faint depression with rounded, often slightly raised, edges. Such marks are obliterated by the tears film. True scratches involving loss of material are caused by quite gross damage and do not occur with reasonable care in use.

With regard to hysterical cases, unless there was a strong therapeutic indication, he did not try to overcome a serious hysterical disability. Very few patients would tolerate anything in actual contact with the cornea. There was, however, a much greater range of corneal sensitiveness than was usually supposed even among normal patients.

Miliary Aneurysms in the Macular Region of the Left Eye.—P. MCG. MOFFATT, F.R.C.S.
 L. W. J., male, aged 37.

History.—Ten years ago he had pulmonary tuberculosis which was treated by pneumothorax. Dr. Andrew Morland reports that he has had no sign or symptom of active disease for at least eight years. The left lung shows much fibrosis, but is unlikely to be causing toxæmia.

In 1943 he consulted me on account of headaches and pain in the eyes on close work. There was considerable hypermetropic astigmatism which was undercorrected, and deficiency of convergence. No abnormality of the fundi was noted. New glasses and a course of orthoptic exercises relieved the symptoms. Early 1946 he complained of frontal headache and aching of the left eye. R. and L. vision with glasses = 6/5, and Jaeger 1. Convergence good, fundi appeared normal. Orthoptic exercises did not help. There was congenital absence of the left frontal sinus but no signs of infection. In April the vision was 6/5 in each eye with glasses, but minute swellings were noted on the vessels surrounding the macula of the left eye.

On examination (20.6.46).—Complaints of a sense of strain after reading for a short time. R. and L. vision with glasses 6/5, and J. 1. Convergence good. The right fundus appears normal, the left fundus shows several very small saccular dilatations on the arterial twigs surrounding the macula. These appear to have increased in number in the past six weeks. Urine: Normal. W.R. and Kahn negative.

The Chairman recalled a case of his own—a man, aged 29, whom he saw about twenty years ago, who had discovered that his vision in one eye was affected. He had some aneurysms, larger than in the case now shown, the largest being about three times the diameter of a main retinal artery, and the smaller ones were perhaps of equal diameter to that artery. They extended over a considerable area of the macula, and the vision was quite markedly affected. The patient only discovered his condition while driving a cart. His and, getting some dust in his good eye, found that he could not see with the other. His condition remained very much the same for a number of years. He had now a more complete central scotoma, with a good deal of diffuse exudate in and around the macula. The case now shown might represent a much earlier or more elementary stage of a similar condition. It would be interesting to see his condition in ten years' time.
